**Abstract.** The underlying processes governing solute transport in peat from an experimentally constructed fen peatland were analyzed by performing saturated and unsaturated solute breakthrough experiments using  $\text{Na}^+$  and  $\text{Cl}^-$  as reactive and non-reactive solutes, respectively. We tested the performance of three solute transport models, including the classical equilibrium convection–dispersion equation (CDE), a chemical non-equilibrium one-site adsorption model (OSA) and a model to account for physical non-equilibrium, the mobile–immobile (MIM) phases. The selection was motivated by the fact that the applicability of the MIM in peat soils finds a wide consensus. However, results from inverse modeling and a robust statistical evaluation of this peat provide evidence that the measured breakthrough of the conservative tracer,  $\text{Cl}^-$ , could be simulated well using the CDE. Furthermore, the very high Damköhler number (which approaches infinity) suggests instantaneous equilibration between the mobile and immobile phases underscoring the redundancy of the MIM approach for this particular peat. Scanning electron microscope images of the peat show the typical multi-pore size distribution structures have been homogenized sufficiently by decomposition, such that physical non-equilibrium solute transport no longer governs the transport process. This result is corroborated by the fact the soil hydraulic properties were adequately described using a unimodal van Genuchten–Mualem model between saturation and a pressure head of  $\sim -1000$  cm of water. Hence, MIM was not the most suitable choice, and the long tailing of the  $\text{Na}^+$  breakthrough curve was caused by chemical non-equilibrium. Successful description was possible using the OSA model. To test our results for the unsaturated case, we conducted an unsaturated steady-state evaporation experiment to drive  $\text{Na}^+$  and  $\text{Cl}^-$  transport. Using the parameterized transport models from the saturated experiments, we could numerically simulate the unsaturated transport using Hydrus-1-D. The simulation showed a good prediction of observed values, confirming the suitability of the parameters for use in a slightly unsaturated transport simulation. The findings improve the understanding of solute redistribution in the constructed fen and imply that MIM should not be automatically assumed for solute transport in peat but rather should be evidence based.

## 1 Introduction

A large pool of leachable Na, Ca and S was introduced in the tailings sand used to construct a fen watershed as part of a novel attempt at landscape reclamation in the oil sands region (Simhayov et al., 2017). The transport of these solutes in groundwater derived from these tailings are likely to affect fen vegetation (Simhayov et al., 2017); thus, a better understanding of the transport processes through peat, and solute accumulation in the rooting zone of the fen, is needed.

The current assumption is that solute attenuation in peat is a result of solute adsorption and mass exchanges between mobile and immobile phases (Hoag and Price, 1997; Rezanezhad et al., 2012). Generally, in *Sphagnum*-derived peat, hyaline cells and their skeletal remnants are thought to account for a large fraction of dead-end pores with distinct pore size density distributions (Weber et al., 2017a, b) and a volumetric moisture content (VMC) between 10 and 20 % (Hayward and Clymo, 1982; Weber et al., 2017a, b). This physical structure, along with surface adsorption of reactive solutes (Rezanezhad et al., 2012, 2016) will lead to delayed arrival of solutes which are likely to affect vegetation community development in oil sands reclamation landscapes. The physical and hydraulic properties of undisturbed peat changes along a continuous vertical profile (Weber et al., 2017b; Limpens et al., 2008), whereby deep peat layers are generally more decomposed (Clymo, 1983). In addition to pore-scale effects, the systematic layered heterogeneity common in natural peatlands influences mixing and transport (Hoag and Price, 1997). However, in constructed peatlands, the decomposition gradient is destroyed because of the disruption caused by draining, stripping, transport and placement (Nwaishi et al., 2015).

Solute transport in the subsurface may be subject to physical and chemical non-equilibrium (Nielsen et al., 1986) invalidating the use of the conventional convection–dispersion equation (CDE) to simulate it. Physical non-equilibrium is thought to be a process of a heterogeneous flow field with spatial differences in hydraulic conductivity due to dead-end pores (Coats and Smith, 1964; Zurmühl and Durner, 1996), non-moving intra-aggregate water (Philip, 1968; Passioura, 1971) or stagnant water in thin liquid films around soil particles (Nielsen et al., 1986). In this mobile–immobile model (MIM; Coats and Smith, 1964; van Genuchten and Wierenga, 1976), the liquid phase is partitioned into a mobile and an immobile region. Convective–dispersive transport occurs only in the mobile zone, while solute transport into the immobile region is by diffusion, the rate of which can be determined by experiments and inverse estimation of transport parameters (Vanderborght et al., 1997). In chemical non-equilibrium models, it is assumed that sorption at the pore-water solid particle interface is kinetically controlled (Cameron and Klute, 1977; Nkedi-Kizza et al., 1989). Both parametric non-equilibrium models may additionally account for chemical equilibrium adsorption (Toride et al., 1993).

To distinguish between the governing solute transport process, inverse modeling can provide the necessary information on model parameter estimates and associated uncertainties, and permits the calculation of model performance and selection criteria (Vrugt and Dane, 2006; Iden and Durner, 2008; Weber et al., 2017a). The modeling can be based on measured solute breakthrough experiments of reactive as well as non-reactive solutes (Nkedi-Kizza et al., 1984). In the notation of the convection–dispersion equation, the retardation factor is strictly referred and attributed to equilibrium adsorption (Toride et al., 1995; Šimůnek and van Genuchten, 2008; Šimůnek et al., 2008) and is a function of bulk density, the slope of the adsorption isotherm and volumetric water content (Toride et al., 1995). A problem in deriving a numerical value for the retardation factor during inverse modeling is that it is mathematically directly negatively proportional to the flow.

To the knowledge of the authors, the only literature reports with experiments of NaCl breakthrough on saturated peat columns conducted in the laboratory are from Price and Woo (1988), Hoag and Price (1997), Ours et al. (1997), Comas and Slater (2004) and Rezanezhad et al. (2012). Ours et al. (1997) speculate that the observed prolonged tailing of NaCl is a result of solutes diffusing into immobile zones. However, neither batch adsorption tests with the potential to exclude kinetic chemical sorption are presented nor were solute transport models fitted to breakthrough curves, leaving their conclusions tentative. Hoag and Price (1997) successfully described their observations with the CDE. However, based on an effective porosity ( $n_e$ ) determined by photo imagery, the authors calculated the pore-water velocity by  $v = q/n_e$ , where  $q$  is specific discharge. The method of estimating  $n_e$  from photo-imagery may easily lead to a systematic miscalculation of effective pore-water velocity, resulting in different values of  $v$  than those calculated from total porosity,  $\phi$  or inverse estimation. By estimating CDE model parameters describing non-reactive  $\text{Cl}^-$  breakthrough and keeping  $v$  fixed, their retardation factor ( $R$ ), reflecting  $v_{\text{water}}/v_{\text{solute}}$  was  $> 1$  and close to the ratio of  $\phi$  to  $n_e$ . They attributed the delay in solute transport to physical non-equilibrium processes, whereby solutes diffuse into inactive pores (i.e., solute transfer from the mobile to the immobile region). The approach of Hoag and Price (1997) differs from the classical understanding where diffusion into the immobile zone is described by a kinetic constant, while  $R$  assumes chemical equilibrium of solutes with sorption sites (e.g., Coats and Smith, 1964; van Genuchten and Wierenga, 1976). Rezanezhad et al. (2012) concluded MIM transport is observable on small peat samples. Moreover, parameter uncertainties and correlations are not shown and the performance of the MIM in comparison to the classical CDE is not given, such that a rigorous model selection is not possible. Additionally, acknowledging that  $\text{Na}^+$  and  $\text{Cl}^-$  ions may interact with dissolved organic matter, inducing changes in the

pore size and geometry (Ours et al., 1997; Comas & Slater, 2004) a pretreatment was implemented (see Sect. 2.3.1).

The goal of the study is to expand our understanding of the transport processes in the vadose zone of decomposed peat by testing various transport models and scrutinizing the common assumption that the mobile–immobile transport model best reflects the processes in saturated and unsaturated peat. We approach this objective by conducting lab-based experiments including saturated and unsaturated breakthrough experiments using NaCl.  $\text{Cl}^-$  is generally uninvolved in chemical reactions in peat, except for ultra-saline conditions (Ours et al., 1997), and its counter ion,  $\text{Na}^+$ , is a prominent solute and potential contaminant in the oil sands reclamation landscape (Simhayov et al., 2017). To compare the performance of models, model parameters were estimated using inverse modeling with the CXTFIT v2.0 code (Toride et al., 1995). Comparison was based on a statistical analysis to investigate the information content of the data collected, enabling a careful assessment of the underlying processes. Subsequently, the parameterized models were used to numerically simulate the solute transport in unsaturated steady-state evaporation experiments with Hydrus-1-D (Simunek et al., 2008). We tested if the model selection and parameterization based on saturated experiments can be extended to predict unsaturated solute transport. No further inverse estimation was done for the unsaturated transport of the non-reactive solute except for the Freundlich–Langmuir parameters of the reactive solute. A sensitivity analysis was then carried out to estimate potential errors caused by using parameters derived from saturated transport to simulate the unsaturated case.

## 2 Materials and methods

The peat used for the fen was moderately decomposed rich fen, sedge peat with remnants of *Sphagnum* moss, originating from a donor fen prior to stripping of overburden material to expose the oil sands deposits (Price et al., 2011; Daly et al., 2012; Nwaishi et al., 2015). The donor fen had been drained for 2 years prior and the peat underwent accelerated decomposition due to exposure to oxygen (Nwaishi et al., 2015). Vegetation growth on the drained fen resulted in addition of stems and leaves to the peat. The samples were shoveled into 20 L buckets from a stockpile made by the heavy machinery that removed the peat layer from the donor fen, further disturbing the peat, as it was placed in the fen. The peat has a relatively open structure (Fig. 1), compared to *Sphagnum* peat used in other transport studies (e.g., Hoag and Price, 1997; Rezanezhad et al., 2012).

### 2.1 Research approach

Four soil physical experiments were conducted to estimate the hydraulic properties and solute transport characteristics of the fen peat material. The conducted experiments were (1) transient evaporation, (2) water retention characteristics

using tension disks, (3) saturated breakthrough and (4) unsaturated breakthrough. As previously noted, the peat was sampled from the stock of disturbed peat used to construct the fen; in addition, we carefully removed woody inclusions and intact leaves to homogenize it such that we could ensure minimal variation between samples. The peat was gently, yet thoroughly, mixed and packed into columns (see Appendix A1); no milling or sieving was done. Prior to experimentation, samples were saturated from the bottom in small increments, over a 24 h period, using 18.2 M $\Omega$  cm water (ultra-pure water). All experiments were conducted at a target bulk density ( $\rho_B$ ) of 0.12 g cm $^{-3}$ . Experiments were conducted on triplicates, except for the tension disk experiments, which were conducted on four samples. For the determination of the solute transport properties,  $\text{Cl}^-$  was used as a non-reactive solute and  $\text{Na}^+$  as a reactive solute. All breakthrough experiments were performed using a solution of 200 mg L $^{-1}$   $\text{Na}^+$  and 300 mg L $^{-1}$   $\text{Cl}^-$  corresponding to values measured by Kessel (2016) in the constructed Nikanotee Fen watershed. This solution was prepared by mixing 500 mg of NaCl (1.06404.055, ACS grade, Merck, Germany) per liter of ultra-pure water.

### 2.2 Soil hydraulic properties

To determine the peat soil hydraulic properties, we conducted transient evaporation experiments (Schindler, 1980; Peters et al., 2015; Weber et al., 2017a, b) for the retention properties, supplemented with tension disk experiments (Klute and Dirksen, 1986; McCarter et al., 2017). Tension disk experiments are considered to be a more reliable method to determine the unsaturated hydraulic conductivity in the wet range, because transient evaporation experiments contain limited information at pressure heads between 0 and –60 cm for the unsaturated hydraulic conductivity curve (Peters and Durner, 2008). Water retention and unsaturated hydraulic conductivity data were obtained with the tension disk experiments using 10 cm i.d. and 5 cm high peat samples at –2.5, –5, –7.5, –10, –15, –20 and –25 cm pressure head (h; cm) steps, which was also the order in which the experiment was conducted. Outflow during each pressure step was monitored by scales with an accuracy of 0.1 g and logged at 1 min intervals and the unsaturated hydraulic conductivity calculated with the Darcy–Buckingham equation (Swartzendruber, 1969). The transient evaporation experiments were conducted on the same samples using commercial UMS HYPROP devices (UMS GmbH, Munich, Germany). The water retention and unsaturated hydraulic conductivity data were then used to obtain parameters of the unimodal van Genuchten–Mualem model (van Genuchten, 1980; Mualem, 1976) by inverse modeling. For further details on parameters, the reader is referred to Appendix A.2.

The volumetric water content,  $\theta$ , was determined as the difference between sample weight and the oven-dry mass for samples dried at 80 °C until no difference in weight was mea-

**Figure 1.** Scanning electron microscope pictures of samples of the peat used in this study. (a) Moss with hyaline cells; note cells with intact membrane at bottom right corner and larger pore spaces in bottom left and top right corners. (b) Hyaline cells with membranes missing; the view through the skeleton is evident. Modified from Rezanezhad et al. (2016).

sured (Gardner, 1986). Bulk density was determined as the ratio of dry weight to the original sample volume. Volumetric water content at saturation,  $\theta_s$ , was assumed to be equivalent to the sample total porosity. Saturated hydraulic conductivity ( $K_s$ ;  $\text{cm d}^{-1}$ ) was determined with a constant head test (Freeze and Cherry, 1979) using the flowthrough chambers described below and a hydraulic gradient of 1.

## 2.3 Saturated breakthrough experiments and inverse modeling

### 2.3.1 Sample preparation

Saturated breakthrough experiments were conducted in 10 cm long, 10 cm i.d. Plexiglas<sup>TM</sup> ( $785 \text{ cm}^3$ ) flowthrough chambers, fitted at each end with  $2.5 \times 15 \times 15 \text{ cm}$  high-density polyethylene (HDPE) end plates with silicon gaskets. A polypropylene fiber pad was placed between the plate and the sample to enhance the distribution of the solution beneath the sample (see Appendix A1). The NaCl solute source was a 20 L magnetically stirred solution reservoir pumped at a steady rate of  $5 \text{ mL min}^{-1}$  (a flux density of  $0.064 \text{ cm min}^{-1}$ ) using a peristaltic pump (WT600–3J, LongerPump, China) and the outflow solute concentration monitored continuously (e.g., Skaggs and Leij, 2002). Prior to the breakthrough experiment, the samples were flushed with two chamber volumes of the NaCl solution to reduce potential changes to the pore sizes as a result of swelling (Price and Woo, 1988; Ours et al., 1997) or clogging due to flocculation. Subsequently, the samples were inverted and flushed with ultra-pure water for six chamber volumes to remove the solutes that were introduced. To determine sampling times and the end of the experiment, an electrical conductivity (EC) electrode (11388–372, SympHony, VWR, USA) connected to a portable meter (SP80PC, SympHony, VWR, USA) was used. The EC meter was calibrated using a two-point cali-

bration with 84 and  $1413 \mu\text{S cm}^{-1}$  conductivity calibration solutions (HI-7033 and HI-7031), respectively (Hanna Instruments, USA). EC was checked every 5–10 min depending on the trend observed. Sampling was done with observed changes in EC and the experiment was continued until 1 h after the outflow EC value was similar to the inflow. Samples were collected in 1.5 mL polypropylene micro centrifuge tubes (Z336769, Sigma-Aldrich, USA) and kept frozen until analyzed. Water samples were analyzed for  $\text{Na}^+$  and  $\text{Cl}^-$  using an ion chromatograph (IC) (DIONEX ICS 3000, IonPac AS18 and CS16 analytical columns). Apparatus blank corrections were done as described in Rajendran et al. (2008), where no transport model for the apparatus blank was assumed but correction values generated using hermite cubic splines.

### 2.3.2 Solute transport models

Two different parametric solute transport model types were used to describe the observed breakthrough data of  $\text{Cl}^-$  and a third additional model for the  $\text{Na}^+$  data. We list the model in the order of testing. The first two consisted of the MIM equation (Eqs. 1 and 2; van Genuchten and Wagenet, 1989) and the classical CDE (Eq. 3; van Genuchten and Alves, 1982; Nielsen et al., 1986), and the third is the one-site adsorption equation (OSA; Eqs. 5 and 6; van Genuchten et al., 1974; Nielsen et al., 1986) which was only used for  $\text{Na}^+$ .

The MIM for a non-reactive solute with instantaneous equilibration is given by

$$\beta\theta \frac{\partial c_m}{\partial t} = D \frac{\partial^2 c_m}{\partial x^2} - v \frac{\partial c_m}{\partial x} - \alpha_{\text{MIM}}(c_m - c_{\text{im}}) \quad (1)$$

$$(1 - \beta)\theta \frac{\partial c_{\text{im}}}{\partial t} = \alpha_{\text{MIM}}(c_m - c_{\text{im}}), \quad (2)$$

where  $\beta$  is the ratio of the water content of the mobile region to the total water content;  $\theta$  ( $\text{L}^3 \text{L}^{-3}$ ),  $C_m$  and  $C_{\text{im}}$  are the

concentrations in the water phase of the mobile and immobile regions ( $\text{ML}^{-3}$ ), respectively;  $D$  is the dispersion coefficient ( $\text{L}^2 \text{T}^{-1}$ );  $v$  is the average linear pore-water velocity ( $\text{L T}^{-1}$ ); and  $\alpha_{\text{MIM}}$  is the first-order rate coefficient between the mobile and immobile regions ( $\text{T}^{-1}$ ).

The CDE is given by

$$\frac{\partial c}{\partial t} = \frac{D}{R} \frac{\partial^2 c}{\partial z^2} - \frac{v}{R} \frac{\partial c}{\partial z}, \quad (3)$$

where  $c$  is the concentration of the total water phase ( $\text{ML}^{-3}$ ), and  $R$  is a retardation factor for equilibrium adsorption, which for a non-reactive solute is typically assumed to be 1 (but see Hoag and Price, 1997). In the classical interpretation,  $R$  is related to the adsorption distribution coefficient,  $K_d$  ( $\text{M}^3 \text{L}^{-3}$ ), by  $R = 1 + \rho_B K_d / \theta$ . The MIM reduces to the CDE equation under certain conditions, which can be analyzed by the dimensionless Damköhler number ( $D_a$ ; Wehrer and Totsche, 1995; Vanderborght et al., 1997) (Eq. 4), given by

$$D_a = \frac{\alpha_{\text{MIM}} L}{v(1 - \beta)\theta}, \quad (4)$$

where  $L$  is the column length ( $L$ ). Large  $D_a$  values indicate very fast equilibration between the regions. From inspection of Eq. (4), it becomes clear that  $D_a \rightarrow \infty$ , and as  $\alpha_{\text{MIM}}$  increases,  $D_a$  increases proportionally, signifying instantaneous equilibration; thus, a differentiation between the two regions cannot be determined. Moreover, Parker and Valocchi (1986) showed that the CDE may also be applicable when a considerable part of the solute dispersion is caused by diffusion into the immobile region.

In physical non-equilibrium, the attenuation of both reactive and non-reactive solutes is affected. However, if only the reactive solute shows long tailing, then it can be assumed that chemical non-equilibrium is affecting the flow process. In NaCl breakthrough experiments (Rezanezhad et al., 2012), only  $\text{Na}^+$  showed long tailings in fen peat so that the physical non-equilibrium model should not be employed. For this case, first-order kinetic chemical non-equilibrium models may be chosen. One typical model for solute transport in porous media is the one-site adsorption equation which is an expansion of the CDE with the addition of a kinetic adsorption member. It is given by

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial z^2} - v \frac{\partial c}{\partial z} - \alpha_{\text{OSA}} \left[ (R - 1)c - \frac{\rho_B}{\theta} s \right] \quad (5)$$

$$\frac{\rho_B}{\theta} \frac{\partial s}{\partial t} = \alpha_{\text{OSA}} \left[ (R - 1)c - \frac{\rho_B}{\theta} s \right], \quad (6)$$

where  $s$  is the kinetically sorbed concentration to the solid ( $M$ ), and  $\alpha_{\text{OSA}}$  is the first-order rate coefficient between dissolved and adsorbed concentration ( $\text{T}^{-1}$ ) which has been found to be a function of pore-water velocity and cannot be derived by batch experiments alone (Nielsen et al., 1986).

Following the traditional approach for solute transport parameterization in peat (Rezanezhad et al., 2012, 2017), we initially assumed the MIM model and compared it with the performance of the CDE for the non-reactive solute. For  $\text{Na}^+$ , transport parameters were additionally estimated with a one-site chemical adsorption model. The data used for the fitting were averages of three replicates. Parameterization of the model was done with CXTFIT (V2.0; Toride et al., 1995), which minimizes the least squares. We estimated the following parameters:  $v$  and  $D$  for the CDE;  $v$ ,  $D$ ,  $\beta$  and  $\alpha_{\text{MIM}}$  for MIM; and  $R$  and  $\alpha_{\text{OSA}}$  for the OSA model. The estimated  $D$  and  $v$  from the  $\text{Cl}^-$  data fit were used for the  $\text{Na}^+$  simulations, since dispersion is a physical material property, and  $R$  can only be determined if  $v$  is fixed from knowledge of a conservative solute experiment. Using various starting values, we ensured that the global minimum was found. CXTFIT calculates the variance–covariance matrix, which is required for the calculation of the standard errors of the parameters and the parameter correlation matrix.

The root mean squared error (RMSE) was used as an index for model performance calculated for each of the tested models (Eq. 14 in Weber et al., 2017a). The corrected Akaike information criterion (AICc; Eq. 2 in Ye et al., 2008) was used as a method of model comparison where the model with the smallest AICc is to be favored. It is a statistically robust and commonly used index to compare models in soil physics (e.g., Weber et al., 2017a).

## 2.4 Unsaturated breakthrough experiments and sensitivity analyses

### 2.4.1 Sample preparation

The unsaturated solute breakthrough experiments were designed as six steady-state evaporation columns 23 cm high and 10 cm i.d. (Fig. 2). Peat samples were placed in a column constructed with a grooved HDPE base plate with an inlet a silicon washer and polypropylene fiber pad, and open at the top (see Appendix A1). The columns were slowly saturated from the bottom in small increments over 48 h to minimize trapped gas bubbles. Once saturated, the columns were flushed with two column volumes of the NaCl solution to reduce potential changes in hydraulic properties, as previously described. The NaCl flushing was followed by flushing six column volumes of ultra-pure water to remove the  $\text{Na}^+$  and  $\text{Cl}^-$ , with the water overflowing from the top of the sample. Flushing of  $\text{Na}^+$  did not remove all solute, resulting in  $40 \text{ mg L}^{-1}$  of  $\text{Na}^+$  remaining in the time zero samples were taken at the bottom 8 cm of the column. Nevertheless, these concentrations were accounted for in the HYDRUS simulation. Columns were then drained overnight with 0 cm pressure head at the bottom of the sample and connected to a Mariot device containing ultra-pure water. The water table was set to the base of the peat column, and the columns were left to settle for 11 days, after which the columns were

**Figure 2.** Unsaturated column experiment column and water reserve setup.

instrumented with the soil tensiometers and water samplers (further details below).

Each Marriot device was fitted with a low flow 12 V mini water pump to circulate the water within it for 5 min every 2 h to prevent solute stratification. Three Marriot devices were filled with an 8.9 mM solution of NaCl as treatment and three with ultra-pure water. The columns were fitted with four unsaturated soil water samplers at 2.5, 7.5, 12.5 and 17.5 cm above the water table (19.21.05, Rhizon, Rhizonsphere, Germany) and with two tensiometers at 10 cm (LM) 23 cm (UM), to determine if the water pressure deviated from hydrostatic conditions (see Appendix A3). Tensiometers were composed of a porous clay cup and a flexible silicon tube, which was open to the atmosphere. The experiment was run for 120 days; evaporation was calculated based on changes to the water level in the Marriot device (see Appendix A3). The experiment was conducted in a room with controlled humidity maintained at  $\sim 45\%$ , assisted by a fan to mix the air in the chamber. Relative humidity (RH) and temperature were measured every 10 min (ECT, Decagon, USA) (see Appendix A3).

NaCl solution was introduced at the base of the column and drawn upwards by evaporation. Marriot devices were attached to supply water over the bottom boundary for each column. The pressure head at the lower boundary was fixed to a pressure head of 0 cm for the duration of the experiment. Daily values of the water level in the Marriot were measured with a measuring tape, and the evaporative water flux over the upper boundary was calculated by dividing the water lost by the cross-sectional surface area of the column (see Appendix A3).

Pore-water samples were taken weekly from each sample height through the Rhizon samplers. On average, 5.5 mL

of water were drawn from each sampler using a dedicated 30 mL polypropylene syringe (Z683647, Sigma-Aldrich, USA). To ensure equal pull on each sampling point,  $6 \times 4 \times 4$  cm HDPE spacers were fabricated and placed within the syringe body and piston. Only samples from time steps of 0, 21, 42, 63, 84 and 120 days were analyzed. After the experiment ended, the cores were frozen, then sliced to  $\sim 2$  cm thick sections using a band saw. Sections were measured with calipers, weighed and placed in pre-weighed, food-grade and heat-resistant bags. The slices were then thawed and ultra-pure water, twice the weight of the slice, was added to extract the solutes and placed on a table shaker (MaxQ 3000, Thermo Fisher Scientific) for 48 h. All samples were frozen until analyzed for  $\text{Na}^+$  and  $\text{Cl}^-$  via IC at the Biogeochemistry Laboratory at the University of Waterloo (DIONEX ICS 3000, IonPac AS18 and CS16 analytical columns). Results were adjusted to account for the dilution effect of the added water.

#### 2.4.2 Numerical simulations and sensitivity analyses

The steady-state unsaturated evaporation experiment with solute transport was simulated with HYDRUS-1-D (Simunek et al., 2008), which numerically solves Richard's equation for water flow and the solute transport equations. For the water flow, the soil hydraulic properties are the necessary input and were parameterized with a unimodal van Genuchten–Mualem equation using data collected in the tension disk experiments and transient evaporation experiments. The model domain represented the 23 cm high column with a spatial discretization of 0.5 cm.

The lower boundary condition for the water flow was at constant zero pressure representing the water table. The upper boundary condition was a flux boundary based on measured evaporation rates. For the solute transport, the lower boundary was a fixed concentration in the liquid phase and the upper boundary condition was a zero flux. To account for the soil solution sampling (that would otherwise lead to a misrepresentation of water flow and solute transport), we used the root water uptake function in HYDRUS by specifying an individual root at the height of each of the four Rhizon samplers. The applied root water uptake model (Feddes et al., 1978) assumes no salinity stress, no pressure-dependent reduction of given water uptake quantity and a quasi-infinite maximum allowed concentration for passive root solute uptake. The total water volume extracted per sampling day was taken to be equal at each root node.

Dispersion is dependent on the average linear velocity, which in turn is dependent on the water content (Perkins and Johnston, 1963). To date, HYDRUS does not account for a water content dependency of dispersion ( $D(\theta)$ ) in solute transport modeling. Also, this information is not available from the saturated experiment. Therefore, a sensitivity analysis of  $D$  on the model response was done to approximate its quantitative influence on the solute transport. To

**Figure 3.** Soil water retention and hydraulic conductivity curves with measurement results of the transient evaporation experiments (EEts) and tension disk experiments (TDEs) and parameterizations for the unimodal van Genuchten–Mualem model. Negative pressure was used for the retention experiment.

gauge the range of values for the sensitivity analysis, a calculation of the change in  $D$  was performed using data gathered from the unsaturated columns. The calculation used the equation for  $D$  in capillary flow under unsaturated conditions in soils as a function of  $v$ , by Fried and Combarous (1971) (not shown). The equation connects  $D$  to changes in water content and allows the calculation of changes in  $D$  due to measured changes in water content. Comparison of the calculated values provided with a range of change in  $D$ . Calculations indicated that the change in  $D$  ranged from 8 to 15 %. Therefore, to add extra range, the sensitivity analysis for the HYDRUS model was performed using  $\pm 20\%$  and a  $\pm 100\%$  change in  $D$ .

### 3 Results and discussion

#### 3.1 Soil physical properties

The bulk density and porosity of the prepared peat samples in the various experiments was similar (Table 1), indicating a successful sample replication. The retention curve (Fig. 3) does not have the classical shape that would point at discrimination between an active and inactive porosity (Rezanezhad et al., 2016; Weber et al., 2017b). Measured water retention and hydraulic conductivity data closely fit the van Genuchten–Mualem unimodal model with an RMSE of 0.03 and AICc value of  $-342$  (Fig. 3; Table 2). Furthermore, the estimated  $K_s$  value of the unimodal fit ( $106\text{ cm d}^{-1}$ ; Table 2) is similar to the measured value ( $100\text{ cm d}^{-1}$ ; Table 1).

**Table 2.** Parameter results for the soil hydraulic properties function of the unimodal (uni) model saturation function; the parameter names are explained in the text.

| Model | $\theta_r$<br>(–) | $\theta_s$<br>(–) | $a_1$<br>(cm <sup>–1</sup> ) | $n_1$<br>(–) | $K_s$<br>(cm d <sup>–1</sup> ) | $\tau$<br>(–) | $w_2$<br>(–) | $a_2$<br>(cm <sup>–1</sup> ) | $n_2$<br>(–) | $n_p$<br>(–) | RMSE $\theta(h)$<br>(–) | RMSE $\log_{10} K(h)$<br>(cm d <sup>–1</sup> ) | AICc<br>(–) |
|-------|-------------------|-------------------|------------------------------|--------------|--------------------------------|---------------|--------------|------------------------------|--------------|--------------|-------------------------|--|-------------|

3.2 Saturated breakthrough experiment

Cl<sup>–</sup> breakthrough started around ~ 60 min with  $C/C_0 = 0.5$  arriving 97 min from the start of the experiment (Fig. 4). Complete Cl<sup>–</sup> breakthrough ( $C/C_0 = 1$ ) was achieved after 300 min. Similar to Cl<sup>–</sup>, initial Na<sup>+</sup> breakthrough began ~ 60 min from the start of the experiment (Fig. 4). However,  $C/C_0 = 0.5$  was not achieved until ~ 250 min, with only ~ 0.85 breakthrough at the end of the experiment that had prolonged tailing, indicating a non-equilibrium process. The EC curve is similar in shape to that of Cl<sup>–</sup> but took longer to reach the full breakthrough. Attenuation of Na<sup>+</sup> compared to Cl<sup>–</sup> is evident by the greater time until  $C/C_0 = 0.5$  (Fig. 4) and is attributed mainly to the high adsorption capacity of peat (Ho and McKay, 2000). In contrast, Cl<sup>–</sup> attenuation in peat is mainly due to mechanical dispersion and diffusion into dead-end pores and not adsorption (Price and Woo, 1988). The dissimilarity of the EC breakthrough curve to that of Na<sup>+</sup> (Fig. 4) demonstrates the limitation of using EC electrodes as an indicator for solutions containing reactive solutes, flowing through reactive mediums. This limitation is due to enrichment of ions in the solution from the soil and cation exchange with the medium, which changes the solution concentration of the cation of interest; therefore, EC can be a good estimator for non-reactive solutes but is limited as an indicator for cation transport (Olsen et al., 2000; Vogeler et al., 2000).

3.3 Unsaturated column experiment

The evaporation rate of the experiment was 3 mm d<sup>–1</sup> (not shown; see Appendix A3). As expected, Cl<sup>–</sup> was transported faster than Na<sup>+</sup>, as evident by the more rapid rise of Cl<sup>–</sup> in the peat profile (Fig. 5).  $C/C_0 = 0.5$  of Cl<sup>–</sup> reached 7.5 cm above the water table within 21 days (Fig. 5a) and by 42 days  $C/C_0 = 0.5$  reached 17.5 cm (Fig. 5a). Complete breakthrough ( $C/C_0 = 1$ ) of Cl<sup>–</sup> was achieved between 63 and 84 days from start of experiment (Fig. 5a). Comparably, Na<sup>+</sup>  $C/C_0 = 0.5$  reached 7.5 cm within 21 days (Fig. 5b). After 42 days, the  $C/C_0 = 0.5$  was located between 12.5 to 17.5 cm from the water table (Fig. 5b). Complete Na<sup>+</sup> breakthrough occurred later than Cl<sup>–</sup>, sometime after 84 days but before 120 days (Fig. 5b). The accumulation of both elements above inflow concentrations ( $C/C_0 > 1$ ) at 17.5 cm after 120 days (Fig. 5b) indicates evaporative accumulation occurred as water molecules left the column while solute molecules remained (Tsyppkin, 2003). Therefore, evap-

**Figure 4.** EC, Cl<sup>–</sup> and Na<sup>+</sup> corrected saturated breakthrough curves in saturated peat over time. Each point is an average of three samples; error bars are standard error of mean. Errors were not accounted for in the fitting.

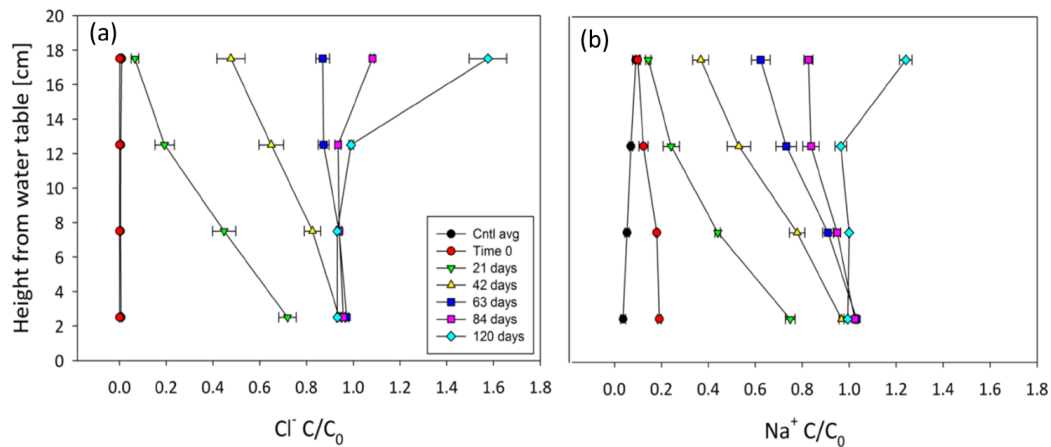

orative accumulation enhances the breakthrough rate as ions remain in the soil while water evaporates, thus producing a faster accumulation rate than if the breakthrough was estimated using a saturated flow system where the solutes would leave the system with the solution. Nevertheless, this effect is a basic product of evaporation-controlled transport (Elrick et al., 1994; Tsyppkin, 2003).

3.4 Simulations

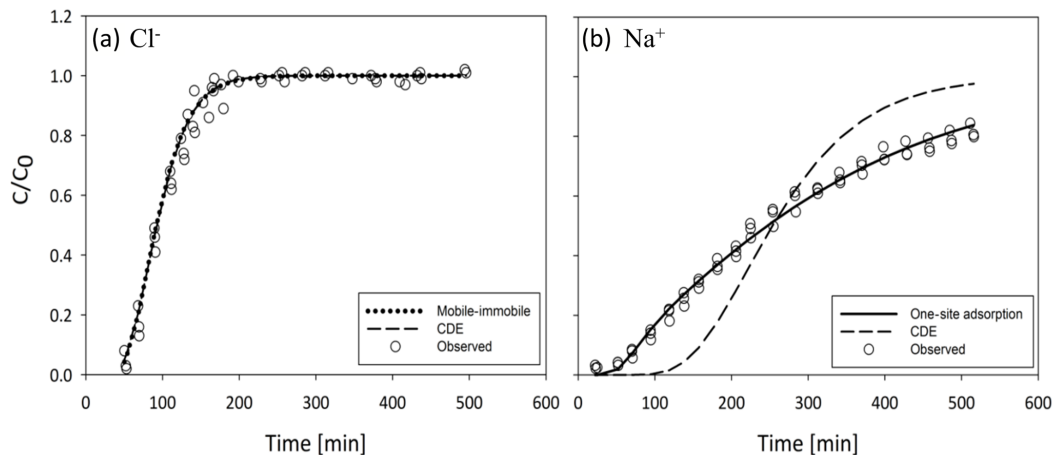

3.4.1 Solute transport model selection

For all transport models, the fitted parameters and associated uncertainties, AICc and RMSE values are given in Table 3. The CDE and MIM model for Cl<sup>–</sup> fit the data well (Fig. 6a) and have identical RMSEs (0.032 mg L<sup>–1</sup>). However, the AICc favors the CDE. Additionally, the MIM model estimated parameters ( $v$ ,  $D$  and  $\beta$ ) show much larger coefficients of variation, with  $\beta$  varying by 1510 % (Table 3). During fitting,  $\alpha_{MIM}$  ran into the CXTFIT internal upper boundary, further suggesting that the application of the MIM is an overparameterization and therefore not suitable. Also, the MIM has two more parameters than the CDE model, which makes the simpler CDE model preferable (Cavanaugh, 1997).

**Figure 5.** Breakthrough curves of solutes in the unsaturated columns profile (a) of  $\text{Cl}^-$  and (b) of  $\text{Na}^+$ . Values presented are averages and whiskers are standard errors. “Cntl avg” represents the average of control measurements; for this aim, all measurements in a specific height were averaged with each point representing 18 measurements. For the treatment, each point is an average of three measurements. Each treatment curve represents a different sampling time from start of experiment. The water table location is at 0 cm.

**Figure 6.** Breakthrough curves of observed values and fitted models of  $\text{Cl}^-$  (a) and  $\text{Na}^+$  (b).

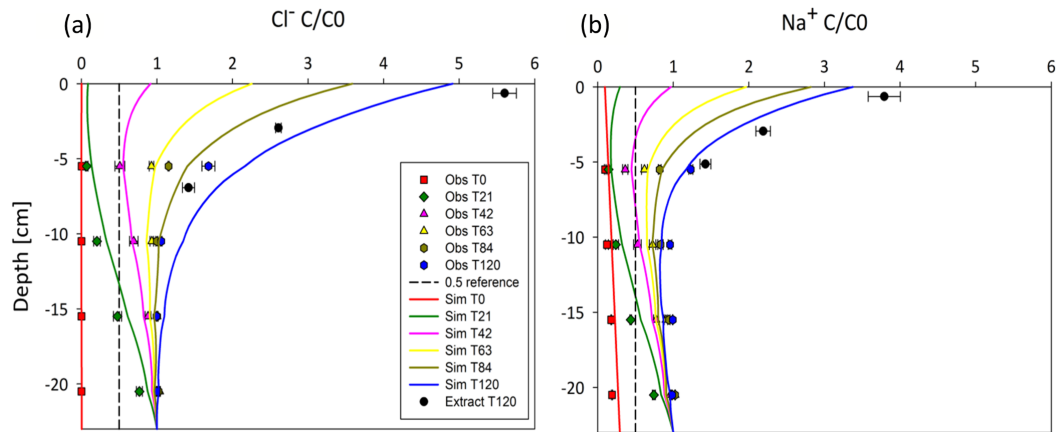

The Peclet number, which is the ratio of advective to diffusive transfer, was 33.9 for the fitted  $\text{Cl}^-$  breakthrough data. In systems with values  $> 2$ , diffusion is considered negligible (Huysmans and Dassargues, 2005). Moreover, with  $\beta \rightarrow 1$  (Table 3), the Damköhler number,  $D_a$ , approaches infinity, so that the equilibration between the mobile and immobile zones is considered instantaneous (Vanderborght et al., 1997; Wehrer and Totsche, 2005). In other words,  $D_a$  indicates the system is not governed by physical non-equilibrium processes, but rather the simpler CDE concept applies. The significance of this result is that the physical non-equilibrium approach may be excluded for these samples and boundary conditions. This exclusion is supported by the instantaneous equilibration between the mobile and immobile zones, indicated by the very large  $\omega$  which was at the upper bound during the parameter estimation. One possible reason for this

finding could be based on the inherent nature of the samples. The peat of the Nikanotee Fen watershed (i.e., the peat used in this experiment) was moderately decomposed sedge peat containing small amounts of *Sphagnum* moss (Nwaishi et al., 2015). It is the *Sphagnum* mosses that contain the hyaline cells (Hayward and Clymo, 1982), which are probably the main cause for the existence of dead-end pores. Therefore, with only a small part of the peat originating from *Sphagnum*, the potential for dead-end pores was small compared to peat that originates mainly from *Sphagnum* moss. Additionally, evidence found in the scanning electron microscope (SEM) scans of the peat used in this study (Fig. 1), shows that the cell membranes have decayed, with only the skeleton of the cell remaining, while the skeleton itself is still intact so water can move much more freely through these structures. These results contradict the hitherto common finding

**Table 3.** Estimated saturated transport parameters and the models’ goodness of fit data. “n/a” – not applicable; N/E – not evaluated: the parameter is at the upper feasible bound of the parameter estimation. Toride et al. (1995) estimated values are presented with coefficient of variation as percentages in brackets; the parameters are explained in the text.

in laboratory studies that breakthrough experiments on peat need to be described by the MIM (Hoag and Price, 1997; Rezanezhad et al., 2012; Liu et al., 2016; Rezanezhad et al., 2017; Thiemeyer et al., 2017). Additionally, this finding is reflected in the fact that a multimodal retention curve was not observable, which would have been indicative for a two-domain flow of solute transport.

Since the CDE model provides a good description of the saturated Cl<sup>–</sup> breakthrough, physical non-equilibrium can be neglected as the underlying process (Table 3; Fig. 6b). Therefore, the non-equilibrium effect observed in the Na<sup>+</sup> breakthrough (Fig. 6b) must be due to chemical processes such as an interaction of Na<sup>+</sup> ions with negatively charged sites on the peat surface. Having shown that the MIM is not parsimonious in its parameters, the robust estimates of  $v$  and  $D$  for the CDE were fixed when fitting the remaining model pa-

rameters of the CDE and one-site adsorption model for Na<sup>+</sup>. First, the CDE was fitted with  $R$  to the Na<sup>+</sup> data; the resulting curve shows that equilibrium adsorption does not fit (Fig. 6b). In comparison, the one-site adsorption model fit well (Fig. 6b) and had a lower RMSE and a considerably lower AICc value (Table 3). Based on the estimated  $R$  value of the one-site adsorption model, the  $K_d$  value of Na<sup>+</sup> was 15.6 L kg<sup>-1</sup>. The parameters from the CDE for Cl<sup>–</sup> and from one-site adsorption for Na<sup>+</sup> were then used for the HYDRUS simulation of the unsaturated columns.

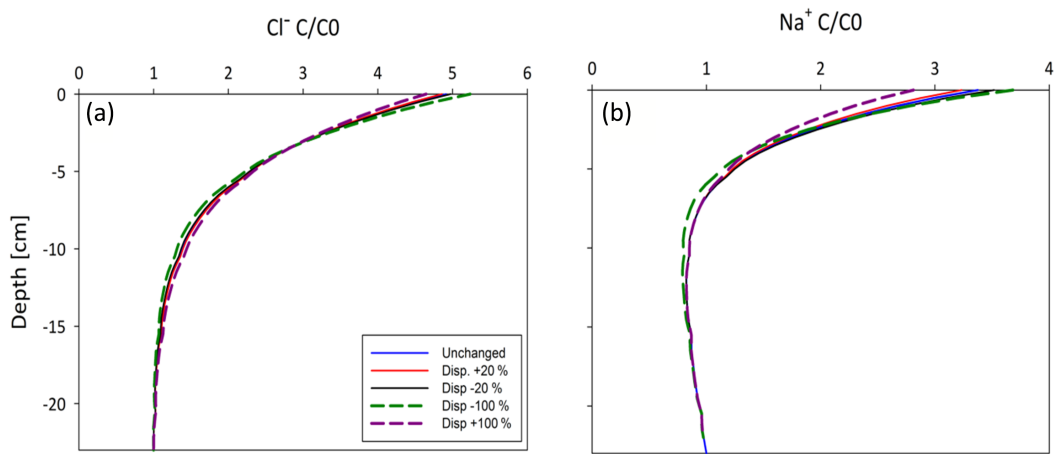

### 3.4.2 Unsaturated column simulations and sensitivity analyses

The HYDRUS predictions of solute concentrations at the four observation points were good for both solutes (Fig. 7), even though the solute transport model parameterization was

**Table 4.** Unsaturated transport parameters used in or estimated by HYDRUS and models’ goodness of fit data. “n/a” – not applicable. Estimated values are presented with the coefficient of variation as percentages in brackets. “Diff. *W*” is the molecular diffusion coefficient of the solutes.

<sup>a</sup> Taken from Appelo and Postma (2004).

**Figure 8.** Sensitivity analysis of unsaturated transport for changes in the dispersion coefficient. (a) in Cl<sup>−</sup> transport, (b) in Na<sup>+</sup>.

based on the saturated experiments. Plotting of the concentrations from the solute extractions for the upper part of the core at the end of the experiment reaffirmed the models’ generally good fit for both solutes (Fig. 7), although in both cases the models underestimate the measured concentration at the very top of the soil profile (Table 4).

Given that the dispersion coefficient for the unsaturated modeling was based on measurements in the saturated flowthrough chambers, a sensitivity analysis was performed with HYDRUS to determine its impact on the simulations. It indicates that a  $\pm 20\%$  change in the dispersion coefficient resulted in a  $\pm 1.2\%$  and a  $\pm 4.1\%$  change in the final concentration of Cl<sup>−</sup> and Na<sup>+</sup>, respectively (Fig. 8). Further, an analysis with a  $\pm 100\%$  change in  $D$  altered the final concentrations by  $-5$  to  $6.5\%$  for Cl<sup>−</sup> and by  $9$  to  $-17\%$  for Na<sup>+</sup>. The analysis demonstrates unsaturated transport is not highly sensitive to changes in the dispersion coefficient under the experimental conditions used. Furthermore, since the differences in water contents were not large, ranging between  $0.93$  at full saturation to  $0.84$  at the top of the column, it is likely that the actual hydrodynamic dispersion did not vary significantly.

4 Conclusions

Saturated breakthrough experiments on disturbed peat, taken from stocks used in the Nikanotee Fen, were conducted in the laboratory using conservative and reactive solutes. With this approach, we investigated whether the common assumption of mobile–immobile solute transport process best reflects the transport processes in saturated and unsaturated peat. Based on inverse modeling of time series of measured conservative tracer concentrations and robust statistical evaluation, we found that the MIM model was an overparameterization for Cl<sup>−</sup>, since very good results were found using the simpler CDE.

For this reason, it could be deduced that the Na<sup>+</sup> attenuation, expressed by prolonged tailings in the observed breakthrough in the fen peat, is chemically based, as the physical non-equilibrium (i.e., MIM) approach would have had an effect on both solutes. Hence, we can conclude that Na<sup>+</sup> showed a distinct chemical non-equilibrium adsorption process, which could be described using the OSA model and still fulfilling the requirement of parsimony. The results are in contrast to the commonly accepted MIM behavior of solutes’ breakthrough in peat samples.

The significance of this result is that while reactive solutes may be heavily attenuated in peat, conservative solutes are not necessarily retarded (Hoag and Price, 1997). In the present case, the degraded structure of the peat (Fig. 1)

eliminated many of the enclosed spaces commonly visible in less decomposed *Sphagnum* peat (see Hoag and Price, 1997; Rezanezhad et al., 2016). Measured water retention data were adequately described using a unimodal expression for the underlying pore size distribution, corroborating the finding that a physical dual porosity structure was not present. On a side note, we can attest that the use of EC as an indirect measurement for a reactive solute will result in overestimation of breakthrough if the solute interacts with the solid phase.

This research implies that automatically assuming mobile and immobile regions in peat is incorrect. The sedge peat with remnants of *Sphagnum* moss used in this experiment had relatively few dead-end pores, due to the low content of *Sphagnum* moss with intact hyaline cells. Furthermore, evidence suggests that the peat used has decayed enough to lose the cell membranes but not enough to break the cell skeleton and is likely why the peat lacks the classically assumed MIM regions. The decomposition may have been enhanced by aeration of the peat in the donor fen (Nwaishi et al., 2015). Although we acknowledge that any manipulation of a sample alters it, the prior disturbance (see introduction of the “Materials and methods” section) is likely to have had a significantly greater impact. Furthermore, the peat was not manipulated in a destructive manner such as sieving or milling, and was handled carefully. The reduced inter-sample variability caused by the careful homogenization of the peat improved the certainty in our results and thus our ability to understand the hydraulic properties of the peat. Additionally, it is concluded that transport parameters gathered in saturated breakthrough experiments can be used to simulate transport in slightly unsaturated media under near steady-state conditions. Data gathered show that the accumulation of solutes via evaporation causes concentration to rise quickly above the initial concentration. While these results are valid for the described boundary conditions and initial conditions, the

fate of salt accumulation is not clear under more natural conditions such as complex meteorological evapotranspiration–precipitation cycles with, for example, surface inundation and overland flow export of solutes. Additionally, different salt concentration levels at the lower boundary of the experiment were not investigated, which has been documented in the case of the Nikanotee Fen watershed (Kessel, 2016). As a first assessment of the effect  $D$  has on salt accumulation, a synthetic parameter sensitivity analysis was carried out for  $\text{Na}^+$ . To further understand the rates of the evaporative accumulation, a more complex numerical transport model should be used, including flushing due to precipitation and runoff, using the parameters reported in this study along with various weather scenarios. Considering the complex hydraulic retention and conductivity properties of *Sphagnum* mosses and peat, it is conceivable that a wide range of tested water contents could affect the choice of the underlying transport process. Additionally, the experiment was carried out under steady-state conditions, unlike the complex meteorological patterns in the field. Furthermore, the implications for reclamation projects are that if one of the goals is to enhance solute attenuation, the origin and composition of the peat, its water retention properties along with its decomposition state should be characterized, as not all peats will perform equally. Hence, from the industry perspective, if solute attenuation is the goal, then peat with a larger amount of *Sphagnum* and a confirmed dual porosity structure would be a better choice. Finally, our findings imply that MIM should not be automatically assumed for solute transport in peat but rather should be evidence based.

**Data availability.** The data can be made available upon request to tobias.weber@uni-hohenheim.de.

## Appendix A

### A1 Pictures of saturated and unsaturated experiments

### A2 Soil hydraulic properties

#### A2.1 Measurements of water retention properties

The tension disk experiment (TDE) was conducted on 10 cm i.d. and 5 cm high peat samples at seven different pressure steps under unsaturated unit gradient vertical flow conditions using a tension disk apparatus that used 15  $\mu\text{m}$  Nytex screens to prevent air entry below the air entry pressure ( $\sim 35$  cm) (Price et al., 2008; McCarter et al., 2017). Samples were initially saturated for 48 h and two layers of cheese cloth covered the top and bottom of the sample to maintain the integrity of the surfaces. The pressure steps ( $h$ ; cm) were  $-2.5$ ,  $-5$ ,  $-7.5$ ,  $-10$ ,  $-15$ ,  $-20$  and  $-25$  cm, which was also the order in which the experiment was conducted. During the experiment, outflow was monitored for each pressure step by a scale with an accuracy of at least 0.1 g and logged at 1 min intervals. The experiment stopped when there was no change from past measurements over a 30 min period. After each step, the weight of the sample was determined to enable calculation of the water content. From the outflow, the unsaturated hydraulic conductivity was calculated from the Darcy–Buckingham equation (Swartzendruber, 1969).

#### Saturated hydraulic conductivity

The flowthrough columns (FTCs) were used for the determination of the saturated conductivity ( $K_s$ ;  $\text{cm d}^{-1}$ ), too, which were connected to a Marriot bottle supplying a constant pressure head. The adopted method was a constant head test (Freeze and Cherry, 1979) with a gradient of 0.44. Once the outflow stabilized, it was measured in a 250 mL glass graduated cylinder (S63459, Fischer Scientific, USA) every 2 min over 20 min.

#### Transient evaporation experiment

The transient evaporation experiment (EEt) was conducted on the same samples as the TDE with a 0 cm pressure head at the bottom prior to the beginning of the EEt with the commercial UMS HYPROP device (UMS GmbH, Munich, Germany). The samples had a larger diameter than the UMS HYPROP device so that Plexiglas screens were used at the bottom to seal and prop the sample. The pressure head was directly measured in the middle of the sample, and thus directly related to the calculated water content to obtain the retention information, which is a valid approximation at or near a linear pressure distribution (Becher, 1971). Hence, the evaluation for conductivity is not reliable.

#### Inverse fitting of soil hydraulic properties

The water retention and unsaturated hydraulic conductivity data were used to parameterize soil hydraulic property (SHP) models. We used the unimodal van Genuchten–Mualem model combination (van Genuchten, 1980; Mualem, 1976). We used the analytical expression derived by Priesack and Durner (2006). The soil water retention function is given by

$$\theta(h) = \theta_r + (\theta_s - \theta_r) \Gamma(h), \quad (\text{A1})$$

where  $\theta_r$  is the residual,  $\theta_s$  the saturated water content ( $\text{cm}^3 \text{cm}^{-3}$ ) and  $\Gamma(h)$  (–) the effective saturation given by

$$\Gamma(h) = \sum_{i=1}^k \Gamma_i(h) = \sum_{i=1}^k w_i [1 + (-\alpha_i h)^{n_i}]^{m_i}, \quad (\text{A2})$$

where  $w_i$  is a weighting coefficient between the modal pore size distributions,  $\alpha_i$  ( $\text{cm}^{-1}$ ) and  $n_i$  (–) are shape parameters with constraining and  $m_i = 1 - 1/n_i$ . The unimodal van Genuchten saturation function is obtained by  $k = 1$ . The unsaturated hydraulic conductivity is expressed as

$$K(\Gamma) = K_s \Gamma^\tau \left( \sum_{i=1}^k w_i \alpha_i \right)^{-2} \times \left( \sum_{i=1}^k w_i \alpha_i \left[ 1 - \left( 1 - (\Gamma)^{1/m_i} \right)^{m_i} \right] \right)^2, \quad (\text{A3})$$

where  $K_s$  is the saturated hydraulic conductivity ( $\text{cm d}^{-1}$ ) and  $\tau$  is sometimes referred to as a tortuosity constant, which should be positive.

All parameters were estimated except for  $\theta_s$ , which was set to 0.925, i.e., the porosity value. Estimation was done in R v3.2.1 (R Core Team, 2015) with implementation of the differential evolution optimizer to minimize the sum of squared errors for the retention and hydraulic conductivity curves (Mullen et al., 2011). The estimation of the soil hydraulic properties of the fen peat by inverse estimation was done as described in Peters and Durner (2008). After all procedures were concluded, bulk densities for all samples were determined gravimetrically based on an oven-dry mass basis for samples dried at 80 °C until no difference in weight was measured (Gardner, 1986). From knowledge of the dry weight and experimental system weight, water contents could be calculated for the soil hydraulic properties.

#### A2.2 Statistical parameters

The RMSE is used as a metric to describing the model prediction quality, such that

$$\text{RMSE} = \sqrt{\frac{1}{m} \sum_{l=1}^m (y_l - \hat{y}_l)^2}, \quad (\text{A4})$$

where  $m$  is the number of observations,  $y_l$  is the observed and  $\hat{y}_l$  the model predicted value (solute concentration,

**Figure A1.** Pictures from saturated transport experiment: (a) cleaning and mixing the peat; (b) flowthrough cell plates (the green pad is below the sample, redistributing the water beneath it); (c) packing cell with peat; and (d) flowthrough experiment setup (cells are connected to a pump drawing the solution from a container on a magnetic stirrer).

**Figure A2.** Pictures from the unsaturated transport experiment: (a) columns with peat (note the laptop for scale); (b) Marriot bottles and pumps; (c) columns connected and instrumented (blue caps are the soil pore-water samplers; large tubes are the tensiometers); and (d) slice of a peat column before extraction at the end of the experiment.

water content or hydraulic conductivity). The AICc (Ye et al., 2008) was also used as a method of model comparison where the model with the smallest AICc is to be favored. Applications so soil hydrological model testing can be found

in Weber et al. (2017a, b).

$$\begin{aligned} \text{AICc} = & m \ln \left( \frac{1}{m} \sum_{l=1}^m (y_l - \hat{y}_l)^2 \right) + 2n_p \\ & + 2 \frac{n_p(n_p + 1)}{m - n_p - 1} + C, \end{aligned} \quad (\text{A5})$$

**Figure A3.** Measured temperature and relative humidity during the unsaturated column experiment. Each point is a daily average of 144 measurements and corresponding standard error.

where  $n_p$  is the number of parameters of a respective model.

Estimation of model parameters was done by minimizing the sum of squared errors for the retention and hydraulic conductivity curves in R.3.2.1 (R Core Team, 2015) with an implementation of the differential evolution optimizer (Mullen et al., 2011) by adopting the multi-objective function as described in Peters and Durner (2008).

### A3 Unsaturated experiment conditions

Ambient conditions in the chamber where the experiment was conducted were stable with an average temperature of  $\sim 25 \pm 1^\circ\text{C}$  and an average RH of  $41 \pm 0.02\%$  (Fig. A3.1). Additionally, water pressure profile in the soil did not vary much for each column; soil water pressure above the water table averaged  $-10.7 \pm 0.5\text{ cm}$  for the low meter and  $-19.5 \pm 0.5\text{ cm}$  for the high meter (Fig. A3). Furthermore, data from all columns were in a similar range (Fig. A4), meaning the columns were reasonable replicates in soil water pressure.

Moreover,  $E$  data strengthen the conclusion that the columns were decent replicates with an overall low fluctuation in values averaging at  $0.27 \pm 0.05\text{ cm d}^{-1}$  (Fig. A5).

**Figure A4.** Soil water pressure measurements over time. The water table is marked at 0 cm. Values around the  $-10$  cm mark are from the low pressure meters of all six columns; values around  $-20$  cm are from the high pressure meters.

**Figure A5.** Calculated ET during the experiment. Data presented are for each column separately (color coded; see legend).

**Competing interests.** The authors declare that they have no conflict of interest.

**Acknowledgements.** The authors would like to thank Harmen Vander Heide, Dan Beaver, Andrew Urschel, Scott Ketcheson, Eric Kessel, Tasha-Leigh Gauthier, James Sherwood, Corey Wells and Vito Lam for their help with logistics, fabrication and analysis. Additionally, the authors thank Mazda Kompanizare, Behrad Gharedaghloo, Fereidoun Rezanezhad and Sascha Christian Iden for their advice. Funding from the following sources is gratefully acknowledged: Natural Science and Engineering Research Council Collaborative Research and Development (NSERC-CRD), Suncor Energy Inc., Shell Canada Limited and Esso Imperial Oil Limited and the German Academic Exchange Service.
