Abstract. Transfer of organic carbon from topsoil horizons to deeper horizons and to the water table is still little documented, in particular in equatorial environments, despite the high primary productivity of the evergreen forest. Due to its complexing capacity, organic carbon also plays a key role in the transfer of metals in the soil profile and, therefore, in pedogenesis and for metal mobility. Here we focus on equatorial podzols, which are known to play an important role in carbon cycling. We carried out soil column experiments using soil material and percolating solution sampled in an Amazonian podzol area in order to better constrain the conditions of the transfer of organic carbon at depth. The dissolved organic matter (DOM) produced in the topsoil was not able to percolate through the clayey, kaolinitic material from the deep horizons and was retained in it. When it previously percolated through the Bh material, there was production of fulvic-like, protein-like compounds and small carboxylic acids able to percolate through the clayey material and increase the mobility of Al, Fe and Si. Podzolic processes in the Bh can, therefore, produce a DOM likely to be transferred to the deep water table, playing a role in the carbon balances at the profile scale and, owing to its complexing capacity, playing a role in deep horizon pedogenesis and weathering. The order of magnitude of carbon concentration in the solution percolating at depth was around 1.5–2.5 mg L⁻¹. Our findings reveal a fundamental mechanism that favors the formation of very thick kaolinitic saprolites.

1 Introduction

At the global scale, soil organic matter (SOM) constitutes the largest terrestrial reservoir of organic carbon (Hiederer and Kochy, 2012), and therefore, understanding its dynamics is crucial for predicting its behavior in the context of climate and land use change. The soil carbon pool studies, initially focused on the A horizon, or in 0–0.3 m depth, were subsequently extended to the upper 2 m (Batjes, 1996) or deeper levels (Montes et al., 2011; James et al., 2014; Pereira et al., 2016). These studies showed that the deep soil carbon – below 0.3 m – can represent a high proportion of the total organic carbon (OC) stored in a profile (30 % to 63 %; Batjes, 1996). Although the interest in better quantifying the deep carbon pool and understanding its dynamics was underlined 10 years ago (Rumpel and Kögel-Knabner, 2011), these

points remain of interest due to a low amount of existing data. In recent works, deep carbon dynamics were inferred from various types of studies using isotopic tracers such as ¹³C or ¹⁴C (Mathieu et al., 2015; Stahl et al., 2016; Douppoux et al., 2017; Balesdent et al., 2018; van der Voort et al., 2019), field measurements (Lucas et al., 2012; Wan et al., 2018; Gibson et al., 2019) and laboratory experiments using column (Guo and Chorover, 2003) or respiration experiments (Fontaine et al., 2007; Lucas et al., 2020). Despite this, little is known about the fluxes and characteristics of organic matter capable of migrating at depth.

In this context, we were interested in equatorial podzols which are known to play an important role in carbon cycling. In Amazonia, these soils store a large carbon pool, estimated at around 13.6 PgC (Montes et al., 2011), and

Pereira et al. (2016) estimated that they contain on average 105.9 kgC m^{-2} , of which 83.2 kgC m^{-2} are in the deep Bh. Doupoux et al. (2017) modeled their genesis and dynamics by considering both total C fluxes and ^{14}C fluxes. They noticed, however, that dissolved organic carbon (DOC) fluxes at depth were not known well enough to constrain the model unambiguously. The DOC fluxes exported and reaching the deep water table were generally either approximated (1) by the analysis of groundwater taken from boreholes or springs situated at the outlet of an elementary watershed of known characteristics or (2) by tracer-aided modeling at the scale of a larger catchment (Birkel et al., 2020). Such data are scarce, and Table 1 summarizes those we found relating to soil systems from tropical or equatorial environments. They show that the solutions which percolate at depth in the soils of tropical or equatorial environments have high DOC contents, varying from 0.3 to 2.3 mg L^{-1} . Regarding podzols, data relating to springs give information on the solutions that flow laterally in the eluvial horizons, but there is very little detailed data on solutions from horizons below the Bh.

In addition to total DOC, the characteristics of the organic species help to understand its mobility and potential degradability. Data from cambisol, Acrisol or Ferralsol catchments (Johnson et al., 2006; Osburn et al., 2017) showed that the DOC percolating at depth was composed of smaller, less aromatic species than DOC from topsoil horizons. Lucas et al. (2012) obtained similar results in solutions from podzolic system that had percolated through, successively, Bh and a thick (2 m) clayey kaolinitic material.

The sampling of deep solutions, often difficult to achieve in hard-to-reach areas such as the equatorial forest, can be effectively supplemented by laboratory simulations, such as column percolation, with the objective of assessing the potential mobility of a given DOC through a soil material. This approach is part of a broader theme addressed by many authors who have been interested in interactions between natural organic matter and minerals, most often related to the mobility of contaminants, such as Hg in Amazonian podzols (Miretzky et al., 2005). Clay minerals, through their sorption properties, promote interactions which condition the transport of DOC in soils and sediments (Jardine et al., 1989; McDowell and Wood, 1984; McCarthy et al., 1993; Kaiser and Guggenberger, 2000). The oxyhydroxides *sensu lato* (oxides, oxyhydroxides *sensu stricto* and hydroxides) of the soil, because of their small sizes and their surfaces with variable charge, also have strong capacities for DOC sorption. Meier et al. (1999) have shown that goethite has a higher sorption capacity than kaolinite and that, for sufficiently low DOC concentrations ($< 20 \text{ mgC L}^{-1}$), the adsorption of large molecules and aromatic groups is favored.

Kaiser and Zech (2000) showed that 85 % to 95 % of the sorption capacity of DOC by the soils they studied (alfisol and inceptisol) was due to the fine fraction ($< 2 \mu\text{m}$), and that the Fe and Al oxyhydroxides *s.l.* were primarily responsible for this sorption capacity. They also showed that these miner-

als promoted the sorption of the more hydrophobic fraction, derived from lignin, while the clay minerals, mainly kaolinite and illite, promoted sorption of the more hydrophilic fraction. Torn et al. (1997) also showed, through the study of Hawaiian chronosequences ranging from andosols to Oxisols, that the organic matter retention capacity of soil materials and the turnover of the adsorbed SOM depended on their mineralogy. Kaolinitic clays are of special interest; they are, at depth, the main adsorbing mineral in high rainfall tropical and equatorial areas where the consequences of the high primary productivity of the rainforest on the carbon cycle are already poorly understood (Grace et al., 2001).

In this framework, we carried out soil column experiments using soil material and percolating solution from an Amazonian podzol area in order to give some insight to the following questions: (1) what differences exist between the dissolved organic matter (DOM) that percolate at depth and the DOM produced in the topsoil, (2) does Bh impact the characteristics and fluxes of DOM percolating at depth, and (3) what are the properties of the deep-percolating DOM with respect to the transport of metals involved in mineral equilibria and, therefore, pedogenesis?

2 Materials and methods

The soil materials used to pack the columns and the percolating solution were sampled in the area, described in Lucas et al. (2012) and Ishida et al. (2014), situated near the São Gabriel da Cachoeira, Amazonas, Brazil. The soil particle size distribution and mineralogical determinations were performed after SOM oxidation using H_2O_2 . Particle size distribution was determined using the Robinson pipette method. Soil organic carbon (SOC) was determined using a carbon, hydrogen, nitrogen and sulfur (CHNS) analyzer (FLASH 2000; Thermo Fisher Scientific). Kaolinite and gibbsite determination were performed by thermogravimetry–differential thermal analysis (TG-DTA), using a Shimadzu simultaneous measuring instrument (DTG-60H). Fe oxides were calculated as Fe_2O_3 after total Fe determination by inductively coupled plasma atomic emission spectroscopy (ICP-AES) on aqua regia digestion extracts.

The columns used were 60 cm long with an internal diameter of 3 cm. To represent the E horizon, we used a quartz sand (Q; pure Fontainebleau sand – commercial; particle size $< 350 \mu\text{m}$). To represent the other horizons, we sampled soil material in Amazonian podzol profiles, namely two sandy Bh material profiles (Bh1 with SOC 4.5 % and Bh2 with SOC 1.7 %) and kaolinitic material (K) from a horizon underlying Bh (Table 2). Between the sampling time and the experiment, the Bh and the kaolinitic materials were kept at field moisture and around 4°C . All materials were passed through a 2 mm sieve and carefully packed in a column to avoid large voids.

Note: ND – non-detected.

These materials were introduced into the columns in layers of 5 cm for kaolinitic material and Bh material and of 10 cm for sand. A 0.1 mm nylon mesh was inserted between each layer to avoid mixing of the phases, at the top of the column to damp the fall of the drops and at the base of the column to avoid suffusion of the material.

A total of six column experiments were conducted according to the arranged percolating device shown in Fig. 1. In total, two columns were packed with a Q-Bh arrangement (Q-Bh1 and Q-Bh2) to observe the DOM transfer through and from the Bh. Then, three columns (Q-Bh1-K(a), Q-Bh1-K(b) and Q-Bh2-K) were packed with a Q-Bh-K arrangement to observe the adsorption of the DOM issued from the Bh by the kaolinitic clay material. Finally, one column (Q-K) was packed with a Q-K arrangement to observe the direct adsorption of the DOM circulating in the E horizons by the kaolinitic clay material.

The input solution was a pH 4.1 black water taken from a spring located towards the center of a podzolic area (0°6'42" S, 66°54'09" W), corresponding to the water of the perched water table circulating in the E horizons. It was kept in air-tight plastic bottles, protected from light and kept at

around 4 °C until the experiment. The input solution was injected at the top of the column by a peristaltic pump to obtain a downward flow of 0.05 mL min⁻¹ for 3 weeks to obtain around 1.3 L of percolate. In parallel, the peristaltic pump was used in suction mode at the output to homogenize the speed and have the same residence time in all the columns. The output solution was sampled every 5 d, giving 5 samples (fractions F1 to F5) for each column of approximately 250 mL each. For each column, a composite sample was formed by proportional mixing of the fractions.

The input solution and the percolates were filtered on a 0.45 µm cellulose nitrate filter previously washed with Milli-Q water and on which blanks made it possible to check the absence of contamination regarding the elements analyzed. DOC, Fe and Al concentrations were determined for each fraction; Si and small organic acids (SOAs; formic, oxalic, malic, etc.) were determined on composite samples.

Input solution and percolates were analyzed according to the following techniques. The DOC was determined by a total organic carbon (TOC) meter (TOC-V; Shimadzu) coupled to an ASI-V automatic sampler. The dissolved organic matter (DOM) was characterized by 3D fluorescence (excitation

emission matrix fluorimetry – EEMF; Hitachi F-4500 spectrometer). This method allows a rapid characterization of fluorophores associated with humic matter and proteins (Chen et al., 2003; Nebbioso and Piccolo, 2013). Major anions and cations were determined by ion chromatography (Dionex DX-120), using $9 \text{ mmol L}^{-1} \text{ NaHCO}_3$ for cation elution and 10 mmol L^{-1} methane sulfonic acid for anion elution. Si, Al and Fe were quantified by ICP-AES. SOAs (formic, oxalic, malic, etc.) were determined and quantified by high-performance ion chromatography (Dionex ICS-3000) coupled to a mass spectrometer (MSQ Plus, Thermo Fisher Scientific) driven by Chromeleon® (version 6.80) and equipped with an AG11-HC guard column (Dionex IonPac) and an AS11-HC guard column ($4 \times 250 \text{ mm}$; Dionex IonPac), using a $25 \mu\text{L}$ loop injection valve. Analysis was performed in a gradient mode (from 1 to 5 mM NaOH in helium-sparged demineralized water in 40 min) at 30°C , with a flow rate set at 0.8 mL min^{-1} . To improve the signal-to-noise ratio of the measurement, an external flow electrochemical suppressor system (ACRS-ICE 500; 4 mm) was added to the analytic system.

The experience was conducted at room temperature (24°C), close to the average temperature in the forest, which is around 25°C (Salati and Marques, 1984).

3 Results and discussion

3.1 Transfers of carbon and major elements

The pH of the percolating solution was 4.1, and it was not modified by passing through the columns. For each column, the variations in DOC concentration between fractions throughout the experiment remained much lower than the differences between the columns and did not exhibit clear trends (Fig. 2); the same evolution was observed for Al and Fe concentrations. There were, therefore, no substantial

Figure 2. Concentration of the DOC in the five fractions (F1 to F5) of the column percolate and in the composite sample. Analytical errors are smaller than the point marks.

changes within a given column experiment in the behavior of the columns, which allows us to discuss the results using the composite sample compositions given in Table 3.

In Fig. 3, we considered that the output of the Q-Bh-type columns corresponded to the input into the kaolinitic material of the Q-Bh-K-type columns. There was a relatively large variation between columns of the same type; the differences between columns of different types, however, remained consistent.

Regarding DOC, the lowest column outlet concentration (1.9 mg L^{-1}) was observed for the Q-K column (Table 3), where 94 % of the carbon introduced at the top of the column was retained; consistently, the upper part of the kaolinitic layer acquired a light brown color. The highest DOC outlet concentrations (17.1 and 11.5 mg L^{-1}) were observed for the two Q-Bh-type columns, which was expected, but where, however, 46 % and 63 % of the carbon introduced were retained. The DOC concentrations at the outlet of the three Q-Bh-K-type columns were intermediate (8.4 , 3.9 and 3.9 mg L^{-1}), corresponding to the retention of 81 %, 88 % and 89 % of the introduced carbon, respectively. In summary, the Bh retained part of the introduced DOC and the kaolinitic material retained most of the DOC of the solution which percolated through. The presence of a Bh, however, increased the proportion of carbon which passed through the kaolinitic material. The nature of the DOM released by the Bh was, therefore, probably different from that of the DOM of the input, i.e., of the black water from the perched water table; this was likely due to a specific microbial activity within the Bh in the columns.

Regarding Si, the column outlet concentrations were always higher (393 to $1182 \mu\text{g L}^{-1}$) than the inlet concentration ($287 \mu\text{g L}^{-1}$); all columns released Si. Percolation by the input solution through the Bh only (Q-Bh), or the kaolinitic material only (Q-K), released Si in similar proportions (outlet

concentrations from 393 to 585 μL^{-1}); the greatest releases (891, 953 and 1182 $\mu\text{g L}^{-1}$) were observed after successive percolation through Bh and kaolinitic material in the Q-Bh-K-type columns.

Aluminum exhibited a very different behavior from that of Si. Percolation through the Bh (Q-Bh) by the input solution (Al concentration 22 $\mu\text{g L}^{-1}$) resulted in high release of Al (490 and 658 $\mu\text{g L}^{-1}$), when percolation through the kaolinitic material only (Q-K) resulted in a partial retention of Al (Al concentration at outlet 17 $\mu\text{g L}^{-1}$). As for DOC, however, the previous percolation through the Bh (Q-Bh-K columns) increased the proportion of Al which passed through the kaolinitic material. The discrepancy between Si and Al behavior shows that these elements were not controlled by a congruent dissolution of kaolinite. The iron concentration pattern was quite similar to Al but with lower concentrations at column outlets. Iron and Al release was different between Bh1 and Bh2, which may be due to the different crystallochemistry of Al- and Fe-bearing minerals.

The behavior of Fe and Al could be explained by the release either of OM complexes (organometallic complexes;

Lucas, 2001; Patel-Sorrentino et al., 2006) or mineral colloids (kaolinite, gibbsite and goethite; Cheng and Saiers, 2015) during percolation through the Bh. These complexes or colloids are subsequently partially retained during percolation through the kaolinitic material. In the Bh output, Si and Al were released in a stoichiometry equivalent to that of kaolinite, which would be compatible with a release of colloidal kaolinite. Recent studies, however, suggested that Si and Al can be transferred as ternary OM-Al-Si complexes (Merdy et al., 2020). During the subsequent percolation through the kaolinitic material, the behavior of these two elements diverged completely; the kaolinitic material retained Al, while it released Si, suggesting that Al was released by the Bh as OM complexes. This interpretation is supported by the high correlation between DOC and Al (Fig. 4). Fe behaved similarly but with a weaker correlation with DOC, which suggests that Al was only transferred as DOM-Al complexes when Fe could also be transferred as mineral colloids.

To assess the consistency of these interpretations, we built a Si-Al diagram considering the data obtained from the stud-

Figure 4. Relationships between DOC and dissolved Al, Fe and Si in column percolates. The cross represents the concentration in the input solution. Values are from composite samples for Si and from individual fractions for Al and Fe.

ied solutions, taking into account the metal complexation by the DOM on one the hand or not taking it into account on the other hand (Fig. 5). The parameters of the dissolved organic matter necessary for the quantification of the complexation were a site density equal to $27 \mu\text{mol mg}^{-1}$ (Lucas et al., 2012) and a DOM–Al conditional stability constant equal to 10^5 (Lee, 1985; Hagvall et al., 2015). The line labeled “Kaolinite 1” corresponds to the stability of kaolinite calculated with the WATEQ4F database, which uses a solubility product (Ksp) identical to that proposed by Tardy and Nahon (1985), after a critical analysis of the literature. The “Kaolinite 2” line uses the solubility product ($\log(\text{Ksp})$) proposed by Grimaldi et al. (2004) to report on equatorial supergene kaolinites substituted in iron and of variable crystallinity.

When the DOM–Al complexes are not considered, Q-Bh1, Q-Bh2 and Q-Bh1-K(a) output solutions seem near equilibrium with kaolinite. However, when DOM–Al complexes are considered, all output solutions are greatly undersaturated with kaolinite and gibbsite. These solutions, which remain aggressive towards the kaolinite, are therefore able to dissolve the upper part of the horizons located under the Bh, promoting the thickening of the profile.

3.2 Fluorescence properties of percolation solutions

Excitation emission fluorescence matrix (EEFM) of input and output solutions are given in Fig. 6. The peak A corresponds to fulvic-like humic compounds, the peak C to humic-like humic compounds and the peak P to protein-like compounds that indicate an active bacterial activity (Coble, 1996); these peaks are characteristic of natural terrestrial DOM. The peaks S1 and S2 have been related to non-humic-like labile matter related to microbial activity (Singh et al., 2010) or to fulvic-like compounds (Stedmon and Markager, 2005).

The EEFM of the input solution was typical of humified DOM with a dominant C peak, a marked A peak and a small P peak. After the input solution has passed through kaolinitic

Figure 5. Situation of the studied solutions in the Si–Al system. Note: red symbols – without considering DOM–Al complexes; green symbols – considering DOM–Al complexes.

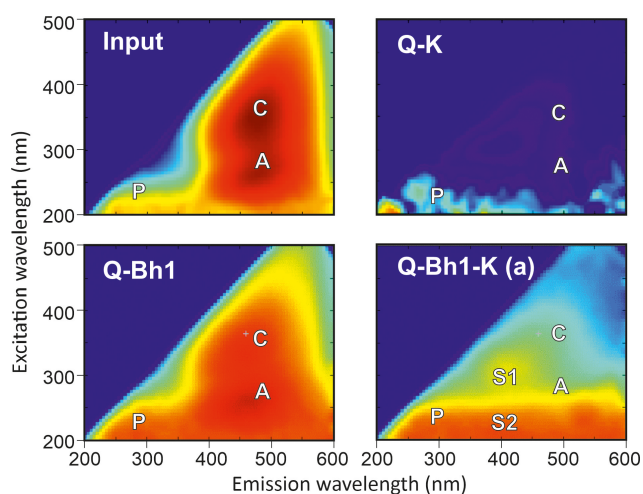

material (Q-K output), there is hardly any humified DOM and a very reduced signal of the protein-like DOM; nearly all fluorescent DOM was retained in the kaolinitic material. After the input solution has passed through the Bh (Q-Bh1 output), there was a reversal of the C/A intensity ratio, which indicates a partial retention of the most condensed DOM in the Bh, and an a higher P peak, which indicates a bacterial activity within the Bh. After the input solution has passed through both Bh and kaolinitic material (Q-Bh1-K(a) output), the DOM exhibited a humified character, more fulvic than humic, and protein-like features.

These observations confirmed that the DOM released by the Bh was different from the DOM of the input solution. The Bh retained most of the humified DOM compounds and re-

leased compounds capable of being transferred through clay materials, which were more fulvic like or protein like, as issued from active bacterial activity.

3.3 Transfer of small organic acids

Chromatography was used to identify the composition of the DOM present in the column experiments. Lactic and malic acids were the only small organic acids found in the input solution at detectable concentrations (Table 4). After the input solution has passed directly through kaolinitic material (Q-K output), 68 % of the carbon from the measured SOAs was retained in the kaolinitic material, and it only remained a low concentration of lactic acid. Percolation of the input solution through the Bh (Q-Bh output) resulted in an increase

in the quantities and variety of SOAs, indicating microbial activity during the experiment, which is consistent with our fluorescence observations. Comparing Q-K and Q-Bh-K outputs shows that a previous percolation through the Bh increased, as for DOC, the proportion of SOA carbon which passed through the kaolinitic material (Fig. 3). This observation is consistent with fluorescence data and strengthens the interpretation that the DOM released by the Bh was different from that of the input solution.

3.4 From experiment to field

To what extent can the above findings be extrapolated to field conditions? The column experiments exhibited differences with typical field conditions. It lasted only 3 weeks, when, at fields under typical conditions, a quasi-permanent water table is perched over the Bh, which has a low hydraulic conductivity. The solution circulating in the E horizon likely percolates very slowly in the Bh throughout the year (Ishida et al., 2014). In the columns, the Bh was reworked, which resulted in a higher hydraulic conductivity and most likely different soil solution contact conditions from that in the field. It was previously dried out, which may result in a change in microbial activity (Denef et al., 2001). Microbial activity is also sensitive to redox conditions. Our column experiments were conducted without controlling the redox potential when deep in situ Bh exhibits reducing conditions (Lucas et al., 2012).

Nevertheless, the column experiment showed negligible variations with time of the percolate characteristics, which suggests a steady state. Results are also consistent with the scarce field data available.

The ratio of input/output average DOC concentration for the Q-Bh-K columns ranged from 0.12 to 0.27, which is in the range of those observed between DOC concentration in E horizons and deep water table (0.13; Lucas et al.,

Figure 7. Main conclusions diagram.

2012) or predicted by podzol genesis modeling (0.14 to 0.35; Doupoux et al., 2017).

In the column experiments, the DOM that percolated through the kaolinitic material had a higher content of small carboxylic acids and of fulvic-like compounds, i.e., it was less aromatic than DOM of the input solution. Such compounds are therefore poorly retained by the kaolinitic material. This is consistent with the observations of Lucas et al. (2012), who found that the DOC of the water table situated under a kaolinitic horizon in a podzolic area had a high proportion of small organic compounds with high complexing capacity.

Field data suggest that the lower boundary of the kaolinitic horizons beneath the Bh moves downward with time (Ishida et al., 2014). This is consistent with the transfer of DOM–Al complexes, which can release Al at depth, promoting kaolinite precipitation. Iron can be transferred in the same way but does not accumulate due to more reducing conditions at depth.

It is, therefore, possible to conclude that percolation through the Bh plays a key role in the geochemistry of the system, by producing compounds able to transfer both DOC and metals through kaolinitic materials.

4 Conclusions

The column experiments led to conclusions shown schematically in Fig. 7. The DOM produced in the acidic upper horizons and circulating in the E horizons would be highly adsorbed, with a complete retention of the humified compounds, if directly percolating through a clayey, kaolinitic material. If this DOM previously percolated through a Bh, it is subjected to transformation in this horizon. The humic-like compounds are retained, and a more fulvic-like, proteinaceous DOM containing small organic acids, which is more likely to percolate through a kaolinitic material, is released.

The DOM that percolates in deep horizons is, therefore, different to the highly humified DOM that circulates in the E

horizon. Microbial activity in an in situ Bh may be different from that observed in the columns, but the input/output C ratio of our experiments was in the range of what has been observed in field or predicted by modeling. A DOC concentration around $1.5\text{--}2.5\text{ mg L}^{-1}$ for solutions percolating through deep kaolinitic horizons appeared, therefore, to be a good order of magnitude. The higher proportion of small organic acids in the solution able to percolate through deep kaolinitic horizons confirmed its ability to transfer metals such as Al or Fe as organometallic complexes, increasing, therefore, the leaching at depth of these elements.

These conclusions strengthen the interpretation given in Ishida et al. (2014), which is related to one of the processes that drive the genesis of tropical podzols. The solution that percolates through the Bh is able to transfer metals through a kaolinitic material, therefore promoting the downward progression of the E/Bh horizons by weathering the upper part of the kaolinitic deep horizons. More widely, our findings reveal a fundamental mechanism that favors the formation of very thick kaolinitic saprolite where pedogenesis could act for a sufficiently long time.

Data availability. The data used in this study are available from the corresponding author.

Author contributions. PM designed the experiments that were carried out by PM and YL. YL, CRM and AJM did the field sampling. BC realized the SOA analysis. PM and YL prepared the paper with contributions from all the co-authors. YL and CRM were the project leaders in France and Brazil, respectively.

Competing interests. The authors declare that they have no conflict of interest.
