Supplement - Methods

Methods for aquatic TDN and DON export
At each forest site, water samples have been taken from a nearby stream with a 2L HDPE bottle. Samples were taken fortnightly (N = 22 for lowland forest, N = 19 for montane forest and N = 5 for Miombo woodland) and discharge was measured at concrete flumes with a fixed width, by measuring water level and discharge with a mechanical flowmeter (General Oceanics Inc, Miami, US). Water samples got filtered through a 0.7 µm glass microfibre filter (Whatman, UK). The filtrated samples were immediately stored in a freezer and transported to Belgium for chemical analysis. NH₄⁺ was determined colorimetrically by the salycialte-nitropusside method (Mulvaney 1996) on an autoanalyzer (AA3; Bran and Luebbe, Norderstedt, Germany). NO₃⁻ was also determined colometrically with the same autoanalyzer in form of NO₂⁻ after reduction of NO₃⁻ in a Cd-Cu column followed by the reaction of the NO₂⁻ with N-l-napthylethlenediamine to produce a chromophore. Total dissolved nitrogen (TDN) was measured by adding 1:1 oxidizing solution of NaOH, H₃BO₃, and K₂S₂O₈ to the sample and autoclave it for 1h at 121°C. This process converted NH₄⁺ and the dissolved organic N (DON) into NO₃⁻ (Lachouani et al. 2010). Yields were calculated by dividing the annual exports by the catchment area. The catchment area was determined using the GPS positions of the flumes and calculating upstream area in a 30-m SRTM derived digital elevation model (DEM) (NASA JPL).

Supplement - Results

Figure S1: δ¹⁵N in topsoil (0 – 20 cm) plotted against the curvature of the sampling spot. Positive curvature values represent concave landforms, while negative values represent convex landforms.
Figure S2: a) Profiles of average bulk N values in g cm\(^{-3}\) for the three different forest sites. b) Profiles of average C:N ratios for the different forest sites. Error bar indicate standard error.
