REVIEW REPORT

Dear editors,

I have reviewed this discussion paper for publication in SOILD. The authors are arguing for inclusion of 'local adaptation' as an essential component of successful ISFM interventions in smallholder farming systems in SSA. First 'local adaptation' is conceptualized and the need for it illustrated with examples of soil fertility patterns within farms, different farm typologies and some limitations to ISFM interventions. The next two chapters describe the impacts of local adaptation on agronomic efficiency (of fertilizer nutrients) at the plot and farm scale. 4 examples are given for the plot scale (liming, secondary and micro-nutrients, tillage, water harvesting) and 2 examples are given for the farm scale (Zimbabwe, western Kenya). The next chapter discusses how (mostly) research on ISFM and local adaptation can be brought to the smallholder farmer and suggests the use of Decision Support Tools and integrated modeling approaches with examples from the NUTMON and NUANCES frameworks and the Nutrient Expert extension support tool. The final chapter draws some conclusions and suggests some research challenges we still face. I liked reading the discussion paper a lot and only have a few suggestions for possible improvement:

Section 2.1, Lines 9-15: I think it would be worth mentioning all soil forming factors that contribute to the formation of the soil-scape (climate, organisms, topography, parent material, time; Jenny, 1941). As it is written now, only long term weathering and soil redistribution seem to be responsible for a typical soil catena (toposequence). Parent material e.g. is very important in determining inherent soil fertility patterns (e.g. poor sandy soils develop on old African basement rocks whereas richer and more clayey soils develop on younger volcanic materials).

> → *REPLY: Agreed – this comment will be integrated in a revised manuscript.*

Section 3.3, Lines 8-11: I am surprised about the association of plough-pan formation with 1:1 clays like kaolinite. Are there other references/data than the Africa Soil Atlas?

> → *REPLY: Kayombo and Lal provide a number of references to articles that have described the widespread occurrence of naturally compacted and hard setting soils in Africa. In their article this is attributed to Alfisols especially, because of their low structural stability and their argillic horizon (or gravelly sub-soil). In the soil atlas these soils are referred to as Lixisols. These soils are prone to structural degradation that may be caused by tilling the soil. The compaction is not necessarily related to the compacting effect of the ploughing per se that you would see in soils with expanding clays, but the effect is the same in that you have a compacted layer below the surface horizon that is tilled and or ploughed.*

Section 5.2. Another good example of a DST/integrated modeling framework is the Tradeoff Analysis model for Multi-Dimensional impact assessment (TOA-MD). This model has been used to support decision making with ex ante impact assessments of alternative practices and/or policies in smallholder agricultural systems in SSA. Examples are the introduction of dual-purpose sweetpotato in western Kenya (Claessens et al., 2009) and tradeoffs in crop residue use (ISFM) in semi-arid Zimbabwe (Homann-Kee Tui et al., 2014).

> → *REPLY: The purpose of the review was not to cover all decision support/modeling tools but provide examples of different tools and approaches and their utility for targeting ISFM technologies. While the TOA-MD approach is interesting, we cannot address it in the paper due to the limited DSTs review scope.*

Congratulations with the paper, a very interesting read!

Minor edits/typos, referring to page and line numbers: 1249, 6-8: I don't understand this sentence
1249, 15: 'if done correctly', what does this mean? Maybe add a reference on correct liming?
1250, 10: have has 14: reverse opposite 21: period missing
1251, 8: common in SSA
1252, 8: under in
1254, 15: was used
1257, 13: period missing 19: on for 20: recommendations
1259, 4: crop-livestock-soil? 6: constraints 10: function of
1260, 11: models 13: seasonal seasonal 17: seasons
1261, 19: explain 22: that with
1262, 15: remove period
1263, 7: a balanced 11: what does 'tertiary level' mean?
1263, 20: and improved germplasm?
1264, 7: changes
1265, 13: others

> → *REPLY: All the above will be addressed in a revised manuscript*

Anonymous Referee #2

1. Overall Comments Provides good synthesis of the status of knowledge on the benefits of integrated Soil Fertility Management (ISFM) that includes fertilizer use at plot level. It goes beyond to highlight the complexity of taking the solutions from plot to farm scale level, complexity that arises from inter – and intra farm variation in soil fertility conditions and household decision process in terms of allocation of their limited resources (fertilizer, manure, labour etc.) and it provides some decision support tool that can be used at both plot and farm scale level in guiding investment ISFM in ways that increase yields and agro economic efficiency. Although the target client of the paper is not articulated, the rich information provided can be used by a wide range of stakeholders, particularly the agricultural research and extension community in sub-Saharan Africa.

2. Specific Comments

State who the target audience of the paper are?

> → *REPLY: The primary target audience is the agricultural R4D community and more specifically those scientists engaging in developing and promoting ISFM options in sub-Saharan Africa. This need was identified through the frequent questions asked at various scientific fora in relation to the specific meaning of 'local adaptation'.*

Would be good to indicate the yield gains at scale, if any, from upscaling ISFM? Given that it is a package of interventions and not a single technology, what would be logical progression in 'localizing its adaptation' in a given region and farming system?

> → *REPLY: The logical progression depends on current practices. Farmers already using improved varieties and fertilizer could, e.g., invest in improving their use efficiency but improved integration of organic resources and adapting application rates to soil fertility conditions. Yield gains at scale will depend on yield gains in individual plots which are quite frequently observed under ISFM, since targeting input use to specific soil conditions is inherent to its definition.*

P.1244 – home gardens. It is worth mentioning the Chagga homegarden of Tanzania that is much published.

> → *REPLY: We are not sure how this would add value. Note that the exact location where this is proposed to be added is unclear because line numbers were not clear from the comments document.*

P. 1248 (3.1 Liming effects) – suggest you indicate the proportion of sub-Saharan Africa's potential agricultural land that is acidic or has al toxicity problems and that requires lime application. This will help put the problem into perspective. Would also be good to mention that the high cost of transportation limits the use of lime. It is generally not an expensive product but its transport is partly because it is often found in areas far from main agricultural production areas. The application rates are also often high, often 2-4 t/ha, adding to its application costs.

→ REPLY: It is known that Al toxicity is inherent to a number of soil types (e.g., Ferrasols, Acrisols) coupled with high rainfall conditions. An estimate of the area occupied by those soil types is about 16% of total land area in sub-Saharan Africa. One could assume that the potential for creating Al toxicity would be in the same order of magnitude. We agree with the reviewer that transportation costs of lime are high, and the further to the mining location the point of delivery is, the more costly it gets. The rate of lime applications is also high, sometimes higher than the range indicated, depending on the level of the Al saturation. However, the current major issue is that the agricultural lime is not even mined in many countries that have the problem. Most lime use has remained at experimental/research purpose. As indicated in the paper, the adoption of liming would depend on the cost effectiveness of the practice, and this would take into consideration the costs suggested by the reviewer. We'll integrate above discussion in the revised manuscript.

Soil Taxonomy used in the paper: suggest both FAO and its equivalent USDA taxonomy are used. This will enhance the readership of the paper.

→ REPLY: We would prefer to keep the FAO/WRB classification since this is the only globally accepted taxonomy.

P.1253 – the statement on effect of water harvesting on AE – N. Would this be true for irrigated rice?

→ REPLY: Water harvesting is not really of relevance to irrigated rice.

P.1257 – Moving knowledge on local adaptation . . . .one comment: Nutrition – good but it is important to state that the negative nutrient balances will result in positive yield gains if fertilizers were applied.

→ REPLY: The translation of negative nutrient balances into yield gains is not only going to depend on increased nutrient application but there are other contributing factors including soil nutrient stocks, status of land degradation, fertilizer rates and balanced nutrient management. We have not included the statement to relate nutrient balances to yield due to many complex factors that determine crop productivity in smallholder farming systems in SSA in addition to increased nutrient use.

State clearly the utility of the model for farm level decision-making. Has any of the models – Nutmon, Nuances, NE, etc. been used at scale by both public and private sector institutions in guiding the role of ISFM practices? If not, what would it take to do that?

→ REPLY: We stated clearly that relatively complex farm-level modeling tools have been uses as 'a platform for research to improve understanding of the complexity of smallholder farming systems.' There are efforts underway to translate the complex modeling tools into simple decision support tools that can be used at scale by extension systems, development programs and the private sector. This includes the example provided on Nutrient Expert. An important step in scaling out is developing simple guidelines for extension systems to refine the general ISFM recommendations and develop targeted ISFM options for specific sites and farms. While there has been limited direct use of DST at large scale, the knowledge generated has been instrumental in raising awareness of import issues including the status and factors driving nutrient depletion and land degradation, the limitations of use of both

organic resource and fertilizers and hence the need for ISFM, and the importance of fertilizer and improve crop varieties as entry points to increasing crop productivity in SSA. This knowledge is the basis of current efforts to implement the 'uniquely African green revolution that recognizes the heterogeneity of Africa's agroecological environments and soils' – Annan 2008.

AfSIS deserves a bit more mention since it is now used widely in Ethiopia for diagnosing soil fertility at scale.

→*REPLY: Recently develop soil mapping approaches used the Africa Soil Information Services (AfSIS) project including compilation of existing soil survey information, data generation using infrared spectrometry, geo-spatial statistical analysis and remote sensing have enabled the rapid and cost effective development digital soil maps. This has offered opportunities to accelerate data collections for accurate diagnosis of soil fertility constraints and improve targeting of technological options. AfSIS has supported the development of new soil maps for Ethiopia that has been used to develop site-specific fertilizer recommendations for different regions in Ethiopia. We'll integrate this in a revised manuscript.*

3. Conclusion Good but would be great to include the human and institutional capacity development needs to further improve the local adaptation and scale up of ISFM technologies. Is the limited uptake of ISFM technologies related to limited human capacity research and extension? If so, what numbers do we need to train? Some concluding remarks on this issue would add value and enhance the readership of the paper.

→*REPLY: These are very relevant and important issues but beyond the scope of this paper.*

Interactive comment on “Integrated soil fertility management in sub-Saharan Africa: unraveling local adaptation” by B. Vanlauwe et al.
R. Voortman

Dear editors,

A colleague called my attention to the above paper and I take the liberty to provide some comments. In short the authors strive to improve scientific practice in the field of development of fertilizer technologies that are locally adapted and appropriate for Sub- Sahara Africa. This is urgently needed indeed. Overall, I think that the authors could develop their ideas somewhat further, while maintaining theoretical rigour. Doing so may bring great benefits for African farmers. Below I summarize the ideas that come to my mind on this issue.

> *→ REPLY: The paper is not aiming to improve science practice for the development of fertilizer technologies. While fertilizer use is an essential component for ISFM, it is certainly not the only component.*

The authors state that: i) Most of the commonly applied fertilizer in SSA contains mainly N, P, and/or K, which do not replenish SMNs under continuous cropping. ii) But indeed the reverse is more likely to be true: where SMN deficiencies exist, they can limit response to NPK fertilizers. iii) management of Al toxicity has received little attention in recent years in SSA These observations are very true. Given the many research findings in the past, it could be concluded that there has been an over-emphasis on high N and P doses in agronomic research in SSA. These high doses are unlikely to be affordable for African farmers and Figure 3 of the paper also shows that high doses are ineffective in raising yields. The emphasis on N and P as well as the lack of attention for liming materials is also remarkable from the theoretical point of view since the plant content of Ca, Mg and S is usually as high as P and frequently even higher. In addition, even though required in very limited amounts, micronutrient deficiencies can impose serious restrictions on crop yield.

> *→ REPLY: We agree that SMN response may be due in large extent to inherent deficiencies and in many cases limit NP response—yet it is still true that NP(K) fertilizers do not replenish SMNs under continuous cropping—or any cropping, for that matter. We agree with the reviewer that there has perhaps been an over-emphasis in the past on NP nutrition—this manuscript brings to the fore yield constraints related to soil acidity and other nutrients.*

The implication for the development of appropriate fertilizers, at least in my opinion, would be that from the outset the working hypothesis would be that any of the essential plant nutrients can be the most deficient or most toxic. However the authors do not really make that change of mind-set. They still mention: i) Much of the evidence relates to N fertilizer applied to maize as N is the most limiting nutrient in many African soils, ii) Blending commonly available NPK fertilizer with SMNs is a cost-effective process to achieve these benefits. iii) to assess the economics of incorporating secondary and micronutrients into NPK fertilizers iv) In the described nutrient omission trials N and P were not omitted (Figure 6) v) In Section 5.3 Nutrient Expert algorithms are recommended to determine N, P, and K fertilizer requirements under specific field conditions. Such observations and recommendations still constitute an emphasis on N, P and K as being the basics, while the use of other nutrients is considered as something that comes in addition. Theoretically the mere addition of SMNs to NPK is also problematic, because of the many interactions between nutrients where uptake by plants is concerned (antagonisms and synergisms). For instance, on soils low in Cu and Zn it may not be wise, and it is likely to be inefficient, to apply their antagonist P.

> → *REPLY: We agree with the reviewer that much past research has concentrated on NPK, and that this research has been done without consideration of other nutrients and soil acidity constraints. It is highly likely that different optimization results would be obtained from modeling NPK response models if secondary/micronutrient deficiencies and soil acidity constraints were simultaneously addressed. While "theoretically" nutrient antagonisms may occur, it is not our practical experience that this is a serious problem, as we have had positive response in applying for example small quantities (less than 0.5 kg/ha) of Cu and Zn as coatings to diammonium phosphate. Practically speaking, SMNs need to be added somehow, and adding them to NPK fertilizers either as blends or coatings has proven both efficient and economic. N and P were not omitted in the omission trials, because we already knew from both soil analysis and previous experience that N and P were deficient. The objective of these trials was to determine if additional nutrients would substantially improve yield response over current NP recommendations.*

Section 2.1 line 9-15: There are some serious ill-conceived generalizations here that affect the credibility of the paper. The main natural factors determining soil fertility are soil parent rock composition, rainfall amount and time. Weathering of parent rock produces soil and in young soils this is still an ongoing process (there are still weatherable minerals in the soil profile). However soil fertility per se, the type of nutrients and their levels, is initially determined by the original parent rock. Depending on the age of the soil and the amount of precipitation (in combination), the soil fertility may be altered by leaching. Soil nutrients have differential leaching rates and therefore not only the level of nutrients changes, but also the proportions of nutrients present in the soil (stoichiometry). Furthermore, soil types are only infrequently associated with slope position (in case of catena's). This is only the case when parent material is rather homogeneous over larger areas and if this occurs in combination with old-age topography (rather flat). Consequently, hills do not occur. Near the highest position at the interfluves soils are not necessarily gravelly and thin with rock outcrops. This is only the case when pockets of more resistant rock occur in the host rock, as is the case for instance in Sukumaland. In fact, at the top of interfluves soils may be deepest of all. Also, further downslope soils need not be more fertile. In fact lower slopes may be shallow and gravelly just above seepage zones, due to redistribution of iron (laterite gravel). In such landscapes the bottomlands (dambo or mbuga) are also not of alluvial origin: they are not deposited by rivers.

> → *REPLY: We agree that this specific statement is rather general and an over-simplification of reality (although the mentioned example does occur). We do not agree that this affects the credibility of the paper since the main factor affecting soil fertility status that is considered in this paper is related to management practices. Inherent soil fertility is indeed determined by parent rock quality and soil-forming processes but long term soil management practices create important soil fertility gradients. As the work on granite*

sands from Zimbabwe shows (cited in the manuscript) these soil fertility gradients can be created in as short a period as three years.

A similar observation on nutrient gradients as apparently mainly observed in Zimbabwe is in place. Some soils are considered as being degraded and strongly depleted of nutrients and where no significant response to "standard" fertilizer can be observed. At the same time it is mentioned that such soils occur on sandy soils developed from granite. Could it be that such soils are neither degraded and nor depleted (from something that was better), but that they are simply a different soil developed from different soil parent material. Indeed this is what must be suspected in case of soil textural differences. This being the case, one would indeed suspect a different set of nutrient deficiencies.

→ *REPLY: There is no doubt that some of this variation in soil fertility on farm is caused by land use and land management history as the gradients can occur over distances as short as 50 m and detailed investigation has demonstrated that all major soil physical variables (texture, drainage, soil depth) are similar across the gradients (Rusinamhodzi et al, 2013). There is also no doubt that this occurs in many countries with high population densities, including Rwanda, East DR Congo, Northern Nigeria, Burkina Faso, Western Kenya, etc, etc. The example from Zimbabwe shows that good maize yields can be obtained near the homesteads.*

Rusinamhodzi, L., Corbeels, M., Zingore, S., Nyamangara, J. & Giller, K. E. (2013). Pushing the envelope? Maize production intensification and the role of cattle manure in recovery of degraded soils in smallholder farming areas of Zimbabwe. Field Crops Research 147: 40-53.

Section 2.1 line 24-28: This sentence is not clear.

→ *REPLY: This sentence will be rephrased in the revised manuscript.*

Section 3.1 Line 2-3: A potential risk of liming at high rates is that it reduces the availability of all micronutrients except Molybdenum.

→ *REPLY: This is correct; one must take care to lime to a correct level.*

Section 3.1: No mention is made of Gypsum which can reduce Al saturation (to deeper levels than lime), maintain micronutrient availability, decrease surface sealing, improve water infiltration, decreases soil erodibility, allows deeper rooting and improves Ca and S nutrition. For instance in Brazil gypsum is considered a valuable soil ameliorant. In this context it deserves mentioning that the shift in African agronomic research from SSP to TSP is deplorable, because SSP actually contains gypsum (Ca and S). Again, in Brazil about 90 percent of P is applied as SSP.

→ *REPLY: The problem in the African context of gypsum is primarily a matter of economics and availability. Gypsum is generally less available than lime. It is not a cheap source of sulfates or Ca in the sub-Saharan African context as are other available sources such as lime and ammonium sulfate. SSP is a good fertilizer but high transport costs limit its economic use to coastal areas. SSP is actually produced in Kenya and is available in some other countries such as Mozambique.*

Section 3.2 line20: I do not think that it is wise/correct to state from the outset that multiple SMNs are the norm. This will have to be established by research. It would be interesting and very useful though, to investigate if there are unifying principles in the occurrence of multiple SMN deficiencies reflect common parent rock mineralogies that derive from the physical laws of nature of rock formation.

> → *REPLY: We believe SMN deficiencies to be the norm. In the past 3-4 years, large areas of Uganda, Ethiopia (all), Mozambique, Rwanda (all), and Burundi (all) have been mapped, and indeed SMN deficiencies are the norm in these countries. We have also found this to be the norm in smaller mapped areas of Zambia, Kenya, and Tanzania. We see response to SMNs in all of these countries, confirming the soil analyses.*

Section 3.2 line 24: It is also important to know which plant nutrients are present in excess. Therefore, I suggest to change the text 'demonstrating the importance of including all potentially deficient nutrients in an omission trial (Fig. 6)'. To: demonstrating the importance of including all essential plant nutrients in an omission trial.

> → *REPLY: There are many essential plant nutrients, so it only makes sense to include those that are potentially deficient in omission trials, as the trials would become unnecessarily large and complicated. This is easily determined from prior soil analyses. One cannot include an "excess" nutrient in an omission trial—though we do note from soil analyses potentially toxic elements (Mn, Al in acid soils; Fe in flooded soils; Na in high pH soils).*

Section 3.3 line 1-3: All issues mentioned can also be addressed with gypsum, or more properly said by reducing the relative amount of Mg and Na at the exchange complex.

> → *REPLY: This sounds quite unlikely and we know of no published evidence to this effect.*

Section 4.1: One of the questions the text of this section raises with me is the extent to which nutrient and organic matter accumulation is merely a question of human influence. Could it not be that initially these soils were also of inherently better quality and were these therefore preferred for cultivation. It also would appear that the level of resource endowment as among others expressed in manure availability is then not an independent variable. Could it not be that because poor people have only poor soils that the ensuing resource endowment is an endogenous variable, relating to original soil quality. Using resource endowment as an independent factor then sort of represents circular reasoning.

> → *REPLY: Resource endowment operates at a within-community scale where farmers commonly have access to the same (combinations of) soils. As stated above, for the sites where this has been intensively investigated in Zimbabwe there is no evidence that poorer farmers are situated on inherently poorer soils.*

Section 5.1: Would it not be meaningful to involve the farmers in local adaptation. Farmers are likely to avail of knowledge on the diversity of their soils and their spatial distribution. Such knowledge might be a meaningful point of departure for a scientific characterization and subsequent research.

> → *REPLY: Paragraph 3 of the Conclusions section specifically addresses this issue.*

Section 6 line24-27: I fully agree that nutrient omission trials are instrumental for developing site-specific and fine-tuned fertilizer technologies. However they are a first step only. Also this first step can still be improved compared to what is presented in Figure 6. The following questions can be raised. Why are there no all-N and all-P trials reported? The all-dolomite experiment may not be very informative as it contains both, Ca and Mg, and further a host of micronutrients, as well as toxic substances like Cd and U (thus calling for careful consideration of liming). Why have Fe, Mn and Mo not been tried? Moreover, Figure 6 gives only averages across sites. This means loss of information. The responses on individual sites is far more informative, certainly if combined with soil chemical analysis for all essential plant nutrients. Sensible interpretation can then be made. I would also suggest that the subsoil is analyzed, because topsoil properties are always somewhat equilibrated due to nutrient cycling. In fact the differences between topsoil and subsoil themselves may be informative on limitations for nutrient uptake. In this way one would be able to simultaneously address the issue of local adaptation as well as the generalization of overarching principles that are evident in the data collected. Interpretation of results (Figure 6) is also not an easy task, because, for instance, the yield decrease when B is withheld may reflect a B deficiency that is due to high N, K and lime applications, because N, K and Ca are antagonistic with B. Similarly the yield reduction when Cu is withdrawn may result from the Mg, N, P and Zn applied, while in case of Zn the antagonists consist of Ca, Cu, Mg, N and P. It is well possible that with lower levels of notably N, P, K and Ca similar 'All' yields would be obtained without a B, Cu and Zn deficiency to be evident. As such nutrient omission trials are a first entry only that serves to develop hypotheses that require verification, but now within the context of a well targeted research agenda

→ *REPLY: There are many questions here, so each is addressed in turn:*

1. *N and P were not included in omission trials because we knew from soil tests that they were already deficient, and the objective of the trials was not related to NP response. Rather the objective was to see what yield increases could be made over commonly available NP fertilizers.*
2. *Dolomite was the available lime source in Burundi. It is not completely informative as one does not know if the effects are due to Ca, Mg, acid-neutralizing potential, or some combination. But it is informative from the perspective that one can determine if the amendment increases yields and is economic to apply.*
3. *We thoroughly analyzed the available lime source for a host of other nutrients, including Zn, B, Mo, Si, and S, and found no substantial quantities that would meaningfully contribute to plant nutrition.*
4. *Mo probably deserves some consideration; Mn and Fe were not included as they were found to be well within sufficiency ranges in the soil analyses.*
5. *We present averages across sites as a matter of brevity for this publication. All nutrient/amendments mentioned contributed significantly to yields—more details such as the reviewer suggests will be in the publications relating to these trials, which will be submitted in 2015.*
6. *While we have considered the possibility of antagonism, believe that the responses evident in the omission trials are not a product of antagonism. Our working hypothesis is that nutrients shown deficient in a soil test are indeed deficient—those are the nutrients we evaluate in the omission trials. The amounts of nutrients we apply are relatively modest and*

would bring soil levels up slightly but not to excessive levels that might induce severe antagonism. In these particular trials, Cu was applied as a foliar, so we cannot have direct antagonism at receptor sites (the common mechanism for Zn/Cu antagonism). Additionally, we have seen positive response to both Zn and Cu in omission trials applied together as fertilizer coatings. If antagonism were in play between Zn and Cu, we would expect omission of one or the other to increase (rather than decrease) yields. Our experience therefore suggests that antagonism is again not in play. Boron levels are extremely low and we have observed B response (as well as Zn and Cu response) without lime—this is strong evidence that the B response is genuine. More practically, applications of N, P (K) and dolomite in these trials can be best described as modest and necessary—and therefore whether or not antagonisms are induced (and we strongly suspect not for reasons stated above), they still require correction as there is no other option.

7. At the same time, we acknowledge that plant tissue analyses would contribute to better interpretation of trial results.

Generally, it is a pity that no references are made to the Brazilian literature, where ample experience with SMN is reported. Maybe Portuguese is a problem, but there are also papers in English. There is also no reference to relevant French literature. I would recommend: Boyer, J. 1978. Le Calcium et le Magnésium dans les sols des régions tropicales humides et sub-humides. Initiations-Documentations Techniques No. 35, ORSTOM, Paris. Interactive comment on SOIL Discuss., 1, 1239

→ *REPLY: Again, this is a matter of maintaining a degree of brevity appropriate for this manuscript. SMN responses are noted the world over. Indeed we eliminated the majority of citations from SMN research on the African continent itself from an earlier draft.*

Integrated Soil Fertility Management in sub-Saharan Africa: Unravelling local adaptation

Abstract

Intensification of smallholder agriculture in sub-Saharan Africa is necessary to address rural poverty and natural resource degradation. Integrated Soil Fertility Management (ISFM) is a means to enhance crop productivity while maximizing the agronomic efficiency (AE) of applied inputs, and can thus contribute to sustainable intensification. ISFM consists of a set of best practices, preferably used in combination, including the use of appropriate germplasm, the appropriate use of fertilizer and of organic resources, and good agronomic practices. The large variability in soil fertility conditions within smallholder farms is also recognised within ISFM, including soils with constraints beyond those addressed by fertilizer and organic inputs. The variable biophysical environments that characterize smallholder farming systems have profound effects on crop productivity and AE and targeted application of limited agro-inputs and management practices is necessary to enhance AE. Further, management decisions depend on the farmer’s resource endowments and production objectives. In this paper we discuss the ‘local adaptation’ component of ISFM and how this can be conceptualized within an ISFM framework, backstopped by analysis of AE at plot and farm level. At plot level, a set of four constraints to maximum AE is discussed in relation to ‘local adaptation’:

soil acidity, secondary nutrient and micro-nutrient (SMN) deficiencies, physical constraints, and drought stress. In each of these cases, examples are presented whereby amendments and/or practices addressing these have a significantly positive impact on fertilizer AE, including mechanistic principles underlying these effects. While the impact of such amendments and/or practices is easily understood for some practices (e.g., the application of SMNs where these are limiting), for others, more complex interactions with fertilizer AE can be identified (e.g., water harvesting under varying rainfall conditions). At farm scale, adjusting fertilizer applications within-farm soil fertility gradients has the potential to increase AE compared with blanket recommendations, in particular where fertility gradients are strong. In the final section, 'local adaption' is discussed in relation to scale issues and decision support tools are evaluated as a means to create a better understanding of complexity at farm level and to communicate ~~best~~ appropriate scenarios for allocating agro-inputs and management practices within heterogeneous farming environments.

1. Introduction

Integrated Soil Fertility Management (ISFM) is a means to increase crop productivity in a profitable and environmentally friendly way (Vanlauwe et al., 2010), and thus to eliminate one of the main factors that perpetuates rural poverty and natural resource degradation in sub-Saharan Africa (SSA). Current interest in ISFM partly results from widespread demonstration of the benefits of typical ISFM interventions at plot scale, including the combined use of organic manure and mineral fertilizers (e.g., Zingore et al., 2008), dual purpose legume – cereal rotations (e.g., Sanginga et al., 2003) or micro-dosing of fertilizer and manure for cereals in semi-arid areas (e.g., Tabo et al., 2007). ISFM is also aligned to the principles of Sustainable Intensification (Pretty et al., 2011; Vanlauwe et al., 2014), one of the paradigms guiding initiatives to increase the productivity of smallholder farming systems. Sustainable Intensification, though lacking a universally accepted definition, usually comprises aspects of enhanced crop productivity, maintenance and/or restoration of other ecosystems services, and enhanced resilience to shocks. ISFM can increase crop productivity and likely enhances other ecosystems services and resilience by diversifying farming systems, mainly with legumes, and increasing the availability of organic resources within farms, mainly as crop residues and/or farmyard manure.

One of the principles of ISFM – the combined application of fertilizer and organic resources – had been promoted since the late 1980s (e.g., Vanlauwe et al., 2001); because of (i) the failure of Green Revolution-like interventions in SSA and (ii) the lack of adoption of low external input technologies by smallholder farmers, including herbaceous legumes-based technologies (e.g., Schulz et al., 2001). The combined application of fertilizer and organic inputs made sense since (i) both fertilizer and organic inputs are often in short supply in smallholder farming systems due to limited affordability and/or accessibility, (ii) both inputs contain varying combinations of nutrients and/or carbon thus addressing different soil fertility-related constraints, and (iii) extra crop produce can often be observed due to positive direct or indirect interactions between fertilizer and organic inputs (Vanlauwe et al., 2001). When presenting the 'second paradigm' for tropical soil fertility management 'Overcome soil constraints by relying on biological processes by adapting germplasm to adverse soil conditions, enhancing soil biological activity, and optimizing nutrient cycling to minimize external inputs and maximize their use efficiency', Sanchez (1994) had already highlighted the need to integrate improved germplasm, a second principle of ISFM, within any improved strategy for nutrient management.

Comment [b1]: This is referred to in the similarity report as longer than 3 lines but cannot be modified since it's a quote

In 2010, with the renewed interest and investment in boosting productivity of African agriculture, following the Abuja Fertilizer Summit and the launch of the Alliance for a Green Revolution in Africa (AGRA), ISFM was reconceptualised with a focus on fertilizer use and the need for maximizing the agronomic efficiency (AE) of its nutrients and consequently the value: cost ratio of its use. This reconceptualization was driven by the recognition that crop productivity in SSA cannot be improved substantially without enhanced fertilizer use and took into account lessons learnt with earlier approaches described above. Agronomic efficiency is defined as extra crop yield produced per unit of fertilizer nutrient applied. Maximizing AE also minimizes the risk that fertilizer nutrients move beyond the rooting zone into the environment and pollute water sources, a problem more typical for high input agriculture and less of a risk for African agriculture (Vanlauwe and Giller, 2006). In this context, applying organic resources in combination with fertilizer can enhance the use efficiency of the latter through a range of direct and indirect mechanisms (Vanlauwe et al., 2001) and the use of improved germplasm is essential to ensure that the supply of nutrients is matched with an equivalent demand for those nutrients. ISFM was thus redefined as *'A set of soil fertility management practices that necessarily include the use of fertilizer, organic inputs, and improved germplasm combined with the knowledge on how to adapt these practices to local conditions, aiming at maximizing agronomic use efficiency of the applied nutrients and improving crop productivity. All inputs need to be managed following sound agronomic principles'* (Vanlauwe et al., 2010). This definition includes a reference to 'adaptation to local conditions'. The revised conceptualization of ISFM also distinguished responsive and non-responsive soils, both soils often occurring within the same farm and the latter being soils on which no significant response to 'standard' fertilizer, or fertilizer that's commonly available and often composed of N, P, and/or K, can be observed (see section 2 below) (Figure 1).

Comment [b2]: This is referred to in the similarity report as longer than 3 lines but cannot be modified since it's a quote

This paper focuses on the 'adaptation to local conditions' of ISFM. 'Local adaptation' refers to specific decision-making processes in relation to the allocation of agro-inputs and management practices at farm and plot level, thereby recognizing production objectives, resource endowments, and farm- and field-specific soil fertility conditions. Although 'local adaptation' was briefly discussed by Vanlauwe et al. (2010), many questions have been raised in relation to the understanding of this component of ISFM and the practices associated with it. The objectives of the paper are therefore (i) to conceptualize the 'local adaptation' of ISFM, (ii) to illustrate the impact of alleviating secondary constraints on the fertilizer nutrient AE at plot scale, (iii) to illustrate the impact of farm-level targeting of inputs and practices on fertilizer nutrient AE at farm scale, (iv) to discuss the consequences of the above on taking local adaptation to scale, and (v) to propose research issues that require urgent attention for ISFM to move to scale.

2. Conceptualization of 'local adaptation'

Since the formulation of the second paradigm (Sanchez, 1994) and with the renewed focus on making fertilizer accessible to and profitable for smallholder farmers, several insights have been gathered that influence fertilizer nutrient AE and thus need to be integrated in the definition of ISFM. Smallholder farming systems in SSA encompass enormous diversity, ranging from semi-nomadic pastoralism in very arid environments to shifting cultivation in the humid tropical forests. Although strongly driven by agro-ecological conditions, a very diverse range of farming systems has been developed through the interplay of, amongst other, local cultures, infrastructure, distance to markets, and socioeconomic opportunities outside agriculture. African farming areas have been described at continental scale under thirteen main categories (Dixon et al., 2001) but such simplification masks huge local diversity, which makes generalization of productivity-enhancing recommendations for SSA problematic (Giller, 2013). Nevertheless~~, and perhaps surprisingly,~~ repeating patterns can be observed across different African farming systems that have important implications for ISFM.

2.1. Patterns of soil fertility conditions within smallholder farms

First of all, ~~two~~ a number of ~~main~~ factors determine the fertility of soils: (i) parent material, (ii) soil formation processes like weathering operating at a time-scale of thousands of years and (iii) human management operating over much shorter time scales. The processes of soil formation and of soil redistribution through erosion and deposition give rise to the soil-scape with typical patterns of soil types associated with slope position across the landscape. Soils ~~are often~~ can be more gravelly and thinner with rock outcrops close to hill tops, with more fertile soils in mid-slope positions and fertile, alluvial soils in the valleys. Superimposed on the soil-scape is a pattern created by human management. Apart from a few exceptions, such as the home-garden agroforestry systems of southern Ethiopia (Abebe et al., 2007), intensive sedentary agriculture is less than 100 years old in the majority of SSA and has been changing rapidly with very rapid growth of human population. Two opposing factors have driven the development of patterns of soil fertility (Giller et al., 2006). On the one hand, increasing pressure on land and the disappearance of fallows have led to intensive cropping which in turn depleted the soils of nutrients. On the other hand, nutrients, concentrated through manure, have been applied to part of the farm – often the fields close to the homestead. These opposing processes give rise to patterns of soil fertility, as depicted conceptually in Figure 2. For instance, in the 'ring management' pattern in West Africa a circle of more fertile soil close to houses is surrounded by poor soils and then increasingly fertile soil with distance from the settlement as bush fields further from the village are cropped less frequently (Prudencio, 1993; Ruthenberg, 1980). In the Bukoba region of Western Tanzania, cattle were used to harvest nutrients to develop fertile banana-coffee-food crop gardens (*bibanja)* in a sea of extensive grasslands (*rweya*) (Baijukya et al., 2005). The reasons that farmers concentrate their nutrient resources on the home fields are several: the home field provides grain for the food security of the household, nutrient resources are often in short supply and insufficient to apply to all of the fields, the home fields are less susceptible to theft, and it is more convenient and requires less labour to transport manure (Misiko et al., 2011).

Fertile home fields need only maintenance fertilization to achieve good crop yields, and crop response to fertilizer in strongly-depleted soils is often weak due to a suite of nutrient deficiencies (Figure 3; Vanlauwe et al., 2006). For example, on depleted outfields on sandy granitic soils in Zimbabwe crop response to N and P fertilizers was limited by deficiencies of Zn, Ca and Mg and K (Zingore et al., 2008). Such depleted fields have been described as 'non-responsive soils', or soils that have been degraded to an extent that the application of NPK fertilizer does not result in increased crop productivity (Vanlauwe et al., 2010). Such soils are common in densely populated areas where mineral and/or organic inputs are in short supply and the generation of non-responsiveness can be a combination of chemical (e.g., soil acidification, micro-nutrient deficiencies), physical, (e.g., topsoil erosion, hardpans) and/or biological (e.g., soil-borne pests and diseases) mechanisms. Obviously, the AE of fertilizer nutrients applied on non-responsive soils is very low to nil and crop yield increases agronomically and/or economically insignificant.

2.2. Farmer typologies, resource endowments, and production objectives within smallholder farming communities

A second commonly observed pattern is the diversity of resource endowments and farm types within farming communities (Figure 2; Tittonell et al., 2010). Drivers operating at different scales generate a diversity of farming households in relation to available on- and off-farm resources and production objectives. Whereas relatively poor families often cultivate more degraded soils (Tittonell and Giller, 2013), families with a relatively higher resource endowment have more options to purchase and allocate fertilizer and organic inputs across the various plots within their farms. The latter are also usually less risk-averse and thus more open to explore alternative agricultural practices within their farm. Soil fertility gradients are often clearest on farms of intermediate resource endowment, as conceptually depicted in Figure 2. Besides access to resources farmers have different production objectives. For instance, in western Kenya Tittonell et al. (2005a) identified that some small farms were owned by wealthy households who had external income from pensions or remittances and for whom farming is not their primary income. Such households are not expected to consider agricultural investments a priority. In contrast, well-resource endowed farmers with large areas of land make a relatively good living from farming. Poor households with very small farms have limited access to resources, often selling their labour to other households, and are thus expected to apply less ~~(~~or no~~)~~ agro-inputs on their farms.

2.3. Limitations of improved germplasm and organic resources to maximize fertilizer AE

Organic resources can enhance the AE of fertilizer nutrients through a number of mechanisms, including ‘direct’ (e.g., temporary N immobilization) and ‘indirect interactions (e.g., temporary alleviation of soil acidity constraints and supply of other yield-limiting nutrients) (Vanlauwe et al., 2001). Improved germplasm can equally enhance AE of fertilizer nutrients by ensuring a higher demand for applied nutrients. For certain constraints, however, organic resource application and improved germplasm are not a suitable solution and other amendments or practises are required (Table 1). For instance, removing a hard pan that restricts crop root growth will require deep ploughing in most cases (though in some cases, the use of deep-rooting trees or grasses could be a solution) (Amézquita et al., 2004; Vanlauwe et al., 2005). For instance, alleviating soil acidity constraints beyond a single season can only be achieved through the incorporation of the right amount and quality of lime. Many observations support positive interactions between water and nutrient management practices (Bationo et al, 1998). While in situations with moisture stress, water harvesting practices certainly fit under 'local adaptation', improved germplasm (e.g., drought-tolerant germplasm) and organic resource management (e.g., surface mulch to reduce evaporation) can also assist in alleviating drought-related constraints. The same applies to other constraints reducing the AE of fertilizer nutrients (Table 1).

~~-~~Additional practices or agro-inputs that can alleviate constraints not addressed through improved varieties, fertilizer, or organic inputs, require integration in the ISFM definition. While the efficient use of fertilizer and organic resources is a principle that is universally applicable – because removing crops requires nutrients to be replenished and applied organic inputs mineralize their carbon over time – other constraints are often observed over geographically-limited areas and do not require attention everywhere and all of the time. Thus, such additional practices or agro-inputs are integrated under the 'local adaptation' component of ISFM, operating at plot scale (Figure 4). Secondly, at farm scale, farming households make decisions on where to invest their available resources (capital, labour) within their heterogeneous farms and aligned to their production objectives, risk aversion, and resource endowment. 'Local adaptation' thus also refers to decisions and recommendations in relation to the types and quantities of agro-inputs and how these are allocated at farm scale (Figure 4).

Having discussed the concept of 'local adaptation' within ISFM, the following sections provide quantitative information on how decisions and practices embedded within 'local adaptation' impact on the AE of fertilizer nutrients.

3. Impact of 'local adaptation' interventions at plot scale on the agronomic efficiency of fertilizer nutrients

This section presents evidence from SSA related to the impact of soil amendments or practices other than introduction of improved varieties or organic resource application on the AE of fertilizer nutrients. ~~Much~~ Most of the evidence relates to N fertilizer applied to maize as N is the most limiting nutrient in many African soils, maize productivity has been observed to decline rapidly in absence of fertilizer application, and ~~much of the~~most research on ISFM has focused on maize. In this section, we present a set of case studies from SSA that illustrate the potential impact of plot-level interventions on fertilizer AE. We do not aim to present a comprehensive literature review or meta-analysis, but rather elaborate the mechanistic interactions between amendments and practices and the AE of fertilizer nutrients. Although many constraints could be considered, we focus on four: soil acidity, secondary nutrient limitations, physical constraints, and drought stress.

3.1. Liming effects on fertilizer AE

Especially ~~I~~in the high rainfall humid zones of SSA, soil acidity and more specifically the presence of relatively high amounts of exchangeable ~~aluminum~~aluminium (Al) ~~saturation~~ is a severe constraint to crop productivity. Some ~~old~~ strongly weathered soils are inherently acidic such as Ferralsols or Acrisols, occupying about 15% of agricultural land in SSA (www.fao.org), while others, such as Arenosols or Lixisols, occupying about 27% of agricultural land in SSA (www.fao.org), are prone to acidification due to inappropriate management practices such as the application of ammonium-containing fertilizer ~~without~~ in absence of crop residue recycling ~~on Lixisols in the West African savannas~~. Al toxicity rather than soil acidity *per se*, is considered to be the major concern of acid soils because it reduces the availability of various nutrients (e.g. P, Ca, Mg) and inhibits root growth of most plants thus limiting nutrient uptake. In order to improve the productivity of acid soils, exchangeable and soluble Al contents need to be reduced. While acid soils may be managed in several ways, including the use of crop species that are tolerant to high levels of exchangeable Al or concentrating relatively high levels of organic resources near the planting hole (Cong and Merckx, 2005), liming is the most established means for correcting Al toxicity (The et al., 2006; Crawford et al., 2008). However, management of Al toxicity has received little attention in recent years in SSA mainly because (i) Al toxicity is believed to be localized to only a few areas particularly of central Africa, where highly weathered and leached soils occur (Crawford et al., 2008), (ii) where the need for liming has been established, the use of lime has been constrained by limited infrastructure for mining lime deposits and transporting the final product.

It has been demonstrated that liming increases the efficiency of fertilizers mainly by (i) increasing the availability of nutrients through favouring processes that govern nutrient release and availability in the soil solution and (ii) enhancing root growth. As for N, plants absorb most N in nitrate (NO_3^-) form and the transformation of ammonium (NH_4^+) to NO_3^-, commonly known as nitrification, is pH dependent, becoming severely reduced at pH below 5. This reduction in nitrification results in decreased N availability for plant uptake (Crawford et al., 2008) but equally in reduced risk for N leaching with NO_3^- being much more prone to leaching beyond the crop rooting zone. Overall, the efficiency of N fertilizers is expected to be reduced at low soil pH, while liming a soil with pH ~~less than~~below 5 stimulates the nitrification process, favouring N availability and ultimately N AE (von Uexkull, 1986; Crawford et al., 2008). High levels of exchangeable Al reduce the availability of P by precipitating or adsorbing P (Uchida and Hue, 2000; von Uexkull, 1986). Liming reduces P adsorption resulting in an increase in P AE upon liming, as demonstrated by a number of trials in East and Central Africa (Figure 5).

In conclusion, appropriate liming practices ~~, if done correctly, is~~ are expected to increase the agronomic efficiency of fertilizers on soils exhibiting high levels of exchangeable ~~or soluble~~ Al by favouring processes towards increased nutrient availability and uptake. Even though lime deposits are available in most countries affected by Al toxicity, the cost effectiveness of lime application, especially in relation to transport and the commonly required high application rates, is likely to negatively affect the adoption of this practice.

3.2. Secondary nutrient effects on fertilizer AE

Secondary and micronutrients (SMNs), including Ca, Mg, S, Zn, Cu, Mn, Fe, B, and Mo, often limit crop growth, especially in soils that have limited reserves and are continuously cropped without returning these nutrients. Most of the commonly applied fertilizer in SSA contains mainly N, P, and/or K which do not replenish SMNs under continuous cropping. Nutrient depletion can be further aggravated by soil acidification which interferes with the availability of specific nutrients. The considerable extent of SMN deficiencies in SSA is gradually becoming apparent. The Ethiopian Soil Information Service is currently involved in mapping the entire country for all nutrients, and has found extensive areas of S, Zn, and B deficiency (www.africasoils.net/EthioSIS). Soil nutrient maps of Rwanda and Burundi show that the majority of the arable land is affected by multiple nutrient deficiencies, including P, Ca, Mg, S, Zn, and B, as well as low soil pH (www.ifdc.org/Nations/Rwanda/; www.ifdc.org/Nations/Burundi/). Significant maize response to S (e.g., Wendt and Rijpma, 1997; Weil and Mughogho, 2000), Mg (e.g., Abunyewa and Mercer-Quarshie, 2004), Zn (e.g., Abunyewa and Mercer-Quarshie, 2004; Zingore et al., 2008), Cu (e.g., Lisumu et al., 2006), and B (Wendt and Rijpma, 1997) have been demonstrated across the continent.

Application of secondary and micronutrients can have significant effects on crop yields in sub-Saharan Africa (Table 2), but ~~have~~ has received less attention than the macronutrients N, P, and K, as illustrated by the fact that most fertilizer subsidy programs primarily focus on NPK fertilizers. This may be due in part to a commonly expressed belief that there is no need to address other nutrients while the continent is still struggling to adopt macronutrient fertilizers. But indeed the reverse is more likely to be true: where SMN deficiencies exist, they can limit response to NPK fertilizers. Because SMNs are required in small quantities, addressing these deficiencies can offer farmers an increased return on fertilizer investment, which is a major factor in increasing farmer adoption. One shortcoming of much research on SMN deficiencies in sub-Saharan Africa is that SMNs are often investigated individually, rather than in combination. Multiple rather than individual SMN deficiencies are the norm in much of sub-Saharan Africa. In an omission trial from Burundi (average of 16 sites), attainable yields with balanced nutrient application were >5 Mt ha^{-1} but eliminating either Cu or B limited the response of all other nutrients to 3.7 Mt ha^{-1}, demonstrating the importance of including all potentially deficient nutrients in an omission trial (Figure 6). However, trials that examine response to multiple nutrients are few and far between.

In conclusion, in ~~the~~ those countries in Africa where SMNs have been extensively mapped, multiple SMN deficiencies are the norm rather than the exception. Application of SMNs on soils exhibiting secondary nutrient limitations is an effective way to enhance fertilizer nutrient AE, provided that all limiting nutrients are addressed. Blending commonly available NPK fertilizer with SMNs is a cost-effective process to achieve these benefits.

3.3. Tillage effects on fertilizer AE

Physical constraints can impede crop yield response to fertilizer and reduce AE, mainly by reducing seed germination and root development and limiting water availability through surface crusting, soil compaction, and/or hard pan formation. Hard-setting soils that may also show surface crusting and that are prone to plough-pan formation are common in SSA (Kayombo and Lal, 1993). These characteristics are associated with light textured soils with mainly 1:1 clay minerals (e.g. kaolinite) and low organic carbon content, typical, e.g., for Lixisols that occupy approximately 10% of the cultivable land in SSA (Jones et al., 2013). The deterioration of topsoil physical properties has been associated with mechanically tilled soil in absence of organic residue retention. Kayombo and Lal (1993), for instance, advocated no-tillage with mulch as the most effective method for controlling soil compaction and erosion, especially for humid and sub-humid tropical environments.

In SSA, the discussion on tillage effects is intrinsically linked to the debate on conservation agriculture (e.g., Giller et al, 2009; Vanlauwe et al, 2014), which uses minimal or zero-tillage as one of its principles. Zero or minimum tillage aims at minimizing soil disturbance, reducing soil erosion, improving water infiltration and improving soil structure (aggregate stability), all which potentially improve fertilizer AE. In the 'step trials', conducted by Thierfelder et al. (2013) in Mozambique, Malawi, Zimbabwe and Zambia, which compared minimum tillage, with or without crop residue retention, these practices did not improve fertilizer N-AE (Table 3). Rather, minimum tillage in these experiments resulted in considerable lower yields compared to the conventional tillage treatment (23% for the non-fertilized plots and 13.6% yield reduction on the fertilized minimum-tillage plots). Reduced yields under minimum tillage are commonly observed, especially when no mulch is applied. In Western Kenya, for instance, Paul et al. (2013) showed an average yield reduction of 19.8% on fertilized no-tillage plots with no mulch applied, relative to tilled plots, with yield reduction limited to 3.8% with application of mulch. Similar trends were observed from experiments conducted in Zimbabwe (Mupangwa et al., 2012). Claims of longer-term positive effects of reduced tillage on yield and possibly AE cannot be substantiated. Rusinamhodzi et al. (2011), in a meta-analysis across 26 long-term field studies from around the world, found no evidence of increased maize yields under no-tillage compared with conventional tillage during the first 10 years of cropping. They did find a positive effect of reduced tillage with mulch ~~under~~ in low rainfall environments on light textured soils, a situation very common in southern Africa.

Some physical constraints for crop production can be alleviated by improved tillage methods. Mechanical loosening of the soil is an important method for controlling soil compaction in both humid and sub-humid and semi-arid and arid regions of Africa, with reported substantial effect on grain yield, and even more so with deep ripping and sub-soiling compared with a mouldboard plough (Kayombo and Lal, 1993). Deep tillage or sub-soiling can result in strong increase in AE of fertilizer nutrients. Chaudhary et al. (1985) showed an increase in N-AE obtained on a loamy sand by ploughing to 20 cm using a moldboard plough, sub-soiling at 40 cm depth using a one-tine sub-soiler, and deep digging to 45 cm depth, compared with a disk harrower and tine cultivator alone (Table 4). This effect was more pronounced under irrigated conditions, indicating improved nutrient and water use efficiencies as a result of better root development.

In conclusion, reduced tillage tends to lead to yield reduction thus not improving fertilizer nutrient AE. In the longer term, reduced tillage practices can have a positive effect on infiltration and water holding capacity but only if accompanied by application of mulch and more so under drier conditions. On the other hand, for compacted soils, deep tillage or sub-soiling can improve fertilizer nutrient AE.

3.4. Water harvesting effects on fertilizer AE

Inter- and intra-seasonal rainfall patterns are often irregular and pose another constraint to enhanced fertilizer uptake by crops. With climate change, within and between-season variability in rainfall has increased in recent years (Morton, 2007). While most papers dealing with water harvesting techniques focus on the obvious positive effects on water use efficiency, the few papers addressing nutrient or fertilizer AE mostly pointed to elevated AE values, irrespective whether these are soil-, organic residue or fertilizer derived (Table 5). Most often these effects are interpreted as the indirect effect of the better moisture conditions on improved rooting density, improved nutrient mobility in the rooting zone and a higher microbial activity releasing additional nutrients from soil organic matter or crop residues and manure.

In a small number of papers some less expected effects emerge. Jensen et al. (2003) highlighted the negative effect that water harvesting techniques may have on fertilizer nutrient AE during relatively wet growing seasons. Tied ridging under these conditions apparently ~~leads to a negative effect on~~reduced fertilizer N recovery. Most likely this ~~is~~ was due to either nitrogen losses through denitrification or restrained root activity due to periods of waterlogging. Mashingaidze et al. (2013) observed no-significant effects of basin water harvesting techniques on nitrogen AE in a wet season. In both of these studies ~~there were~~ clear benefits were observed during the more usual weather patterns, entailing periods of drought and water stress. Besides water harvesting techniques, adjusting N applications to season rainfall patterns is another means to reduce nutrient losses and improve fertilizer nutrient AE in semi-arid areas (Piha, 1993).

In conclusion, in most situations with drought stress, water harvesting techniques are expected to increase fertilizer nutrient AE while in relatively wet seasons, such techniques can actually reduce AE. Obviously, the added costs – especially labour costs – need to be weighed against the expected increases in agronomic efficiency.

4. Impact of 'local adaptation' interventions at farm scale on the agronomic efficiency of fertilizer nutrients

This section provides insights in how allocation of resources at farm scale affects farm-level AE values and how household resource endowment interacts with the decision-making processes regarding the allocation of these resources and the ultimate impact on AE values.

4.1. Impact of soil fertility gradients and resource endowment on farm-level productivity and AE: a case study from Zimbabwe

At the farm scale, AE is influenced by a number of interdependent factors, including soil type, landscape position, soil fertility status, and allocation of nutrients. Zingore et al. (2011) investigated the optimal nutrient allocation strategy to maximize maize production at the farm level, taking into account soil fertility gradients and differences in land, livestock and nutrient resource availability between farm types in Murewa, Zimbabwe. Differences in field level ~~agronomic efficiency~~AE, which ~~are~~ were related to soil texture, past management and current nutrient (N, P, manure) application, dictated where resources should be directed preferentially to maximize returns. This was done by ~~, i.e.~~ targeting ~~zones~~ the fields where the highest ~~with high returns~~ AE could be achieved, based on field-level crop growth simulation results~~and avoiding over-supply of nutrients~~~~, i.e. targeting zones with high returns and avoiding over-supply of nutrients~~ (Figure 3). On sandy soils, whole farm production could be maximized by concentrating the available manure on the soils of medium fertility, while mineral (N, P) fertilizer was used most efficiently on the homestead fields (Table 6), where the high soil organic matter content ensures good growth conditions and nutrient availability, , at least in the short term. -- ~~thereby noting that this~~This only applied to high and medium resource endowed households since low resource endowed households did not have such soils. In the long term, the breakdown of organic matter led to a decrease in whole-farm production based on the same input levels. On clay soils, where soil organic matter is better protected against decomposition compared to sandy soils, high yields could be achieved without mineral fertilizer on both home fields and middle fields if manure was applied at high rates (10 t ha^{-1}) (Figure 3). Without manure input, the relatively stable soil organic matter of home and middle fields still ensured high agronomic efficiency of mineral fertilizer (Figure 3, Table 6). Therefore, for both high and medium resource endowed farmers it was most efficient to separate the allocation of manure and mineral fertilizer. Thanks to the higher inherent soil fertility and slower organic matter breakdown of clay soils, the long term whole-farm production did not decrease as strongly as on sandy soils. High, medium and low resource endowed farms produce different grain quantities due to differences in cultivated land area, in patterns of soil fertility and in available manure quantity. Furthermore, the optimal allocation scenario for scarce nutrient resources varied according to soil type, and also according to resource endowment (Table 6). For example, medium resource endowed farmers could maximize their farm-level production and agronomic efficiency by ignoring outfields and concentrating their nutrient resources to home and middle fields. Low resource endowed farmers, who only own outfields, could still increase their production by applying mineral fertilizers to these poor fields.

Across soil and farm types, ~~it is clear that a~~the targeted allocation of nutrient resources resulted in equal or higher farm production and ~~agronomic efficiency~~overall AE than the~~a~~ blanket recommendation (Table 6). This benefit of targeted allocation was more pronounced on medium resource endowed farms (Table 6), where within-farm soil fertility gradients were strongest (Figure 2 Especially on the sandy soils, higher ~~High~~ N ~~and P agronomic efficiency~~AE ~~can be~~ was achieved ~~on home fields~~ by exploiting the soil fertility ~~). High N and P agronomic efficiency can be achieved on home fields by exploiting the soil fertility~~ that has been built up over many years of preferential manure allocation on the home fields. This was done by concentrating most of the mineral fertilizer on the home fields, and allocating the manure on the midfields. Continuing this over several years however would result in a decrease in the soil organic matter content (cf. Rowe et al., 2006), reducing soil fertility and the farm grain production potential (Table 6). Nevertheless, with current farm management (including crop residue removal for livestock feeding) and nutrient constraints, large yield reductions on sandy soils cannot be avoided, due to the net depletion of nutrients and organic matter in these farming systems. ~~On clay soils with slower organic matter decomposition, yield reduction over time is less pronounced (Table 6).~~

4.2. Production objectives, management intensity, and fertilizer AE

Superimposed on the soil fertility gradients are the impacts of differential management. In addition to provision of manure, livestock provide animal traction that can ensure timely ploughing and weeding. Shortage of labour leads to delays in farm operations (e.g. planting, weeding) which cause strong reductions in AE. Field experiments and simulation modelling indicated for the example of Malawian smallholders that weeding twice could double the AE of N as opposed to weeding once (Kamanga et al., 2014). To earn an income to purchase food, poorer households often work for wealthier farmers during periods of peak labour demand leading to delays in crop management and therefore poorer yields in their own fields and food insecurity (Kamanga et al., 2014). Thus, the above-mentioned soil fertility gradients run in parallel with gradients of management intensity (Giller et al., 2006; Tittonell et al., 2007a). For a case study farm in

Western Kenya, Tittonell et al. (2007b) investigated the trade-offs associated with labour and nutrient allocation strategies for varying degrees of investment. In this area of relatively high agricultural potential, allocating most labour and cash resources to the average-fertility fields allowed minimizing the trade-off between food production and resource conservation. Also, the optimal range of labour and nutrient allocation strategies was wide with less investment, but narrowed with increasing cash availability, explaining to some degree the large diversity of farm management and structure in smallholder farming systems. This example from Kenya illustrates that on top of the soil fertility gradients, farm management decisions, influenced by farmers' objectives and production orientation, create another layer of complexity determining AE at the farm level.

Because resources (land, nutrients, labour, cash) are limited on smallholder farms, their allocation to a particular farm component or on a particular moment in time, creates trade-offs between multiple objectives operating at different time scales: e.g. the short-term food production objective as opposed to the longer-term resource conservation objective. Increasing ~~agronomic efficiency~~AE is the objective we highlight in this paper, but to understand farmer decision making, farmers' objectives, the trade-offs between them and the time scales at which they operate are essential as well. For example, farmers who are able to invest in fertilizers and want to maximize income, might apply nutrients in quantities that result in reduced AE, although the extent of this reduction depends on the fertilizer:grain price ratios (Figure 7). Likewise, low resource endowed farmers might operate within the range of maximum agronomic efficiency, in other words, the linear part of the yield to N input curve, because of lack of capital assets to invest in fertilizers. However, although efficient, they still make less money than households that can afford to apply higher fertilizer rates. Hence, if the costs of nutrients lost to the environment are not accounted for, as in the gross margin calculations of Figure 7, higher investment opportunities might result in lower AEs. From this it is clear that the farm scale is the appropriate scale of analysis to understand the important interplay of various objectives affecting the adoption of ISFM interventions.

In conclusion, although the complexity of soil fertility gradients across the landscape and within farms might seem bewildering, it can be reduced to more easily understood concepts as presented in Figure 2. Adjusting fertilizer and organic matter applications to this variability has the potential to increase AE at farm scale compared to blanket recommendations, in particular where fertility gradients are strong. Important to note is that fertilizer application rates to maximize income, are not similar to those maximizing AE for commonly occurring fertilizer:grain price ratios.

5. Moving knowledge on local adaptation to the smallholder farmer

The large spatio-temporal heterogeneity in climate, soil, and socio-economic conditions in smallholder farming systems in SSA presents major challenges for developing 'local adaptation' recommendations. A better understanding of the influence of biophysical and socio-economic factors on the performance of technologies at different scales is necessary to improve targeting of such recommendations.

5.1. 'Local adaptation' and scale issues

Past efforts to develop recommendations for ISFM interventions have mostly targeted regions within countries, with target zones mostly defined by broad agro-ecological conditions, thus negating the importance of 'local adaptation' ~~on~~ for technology performance. Simplification of recommendations based on the performance of single technologies at plot-scale led to development of 'blanket' recommendations that implicitly assume homogeneity of production factors at the landscape, community, and farm level. Results from regional scale analysis have been valuable in informing policy on urgent need to support farmers to access improved seed and fertilizers to resolve soil fertility challenges underlying low crop productivity (e.g. increase fertilizer use to support crop production intensification, which led to the target of increasing fertilizer use in SSA to 50 kg nutrients per ha). Despite a number of cases of successful large-scale dissemination of ISFM technologies, many ISFM technologies have produced limited impact due to poor match between technologies developed at plot scale to the complex socio-economic and biophysical variability that typify smallholder farms (Giller et al., 2006). Effective large scale dissemination of ISFM technologies would require not only appropriate recommendations for the use of fertilizer, manure and improved varieties, but also adaptation of technologies for site-specific biophysical and socio-economic conditions that determine technological performance and feasibility, as conceptualized by the 'local adaptation' component of ISFM.

Refining the scale for targeting ISFM recommendations from the regional scale to landscape/village scale and specific farms and fields is inevitably associated with increasing complexity of the research and data requirements, which presents challenges for developing and disseminating 'best-fit' ISFM technologies that are appropriate for local adaptation. While field-specific soil fertility conditions would be the ideal target for specific ISFM recommendations, large scale recommendations targeting specific fields within farms are not feasible due to the characteristic short-range soil fertility variability and the need for high resolution maps that adequately capture soil fertility differences at scales less than 100 m. Developing precise ISFM practices targeting individual fields is also impractical due to the complex variability of soil fertility within very short distances. Many studies have identified the farm-scale as an important unit for targeting ISFM recommendations. Despite the complexity of smallholder farming systems, farm typology studies have shown repeating patterns of farm-scale variability associated with access and management of nutrient resources, farm sizes and production objectives (see above). This provides opportunities for targeting technologies to farm types or resource groups, and to 'field types' within farms to optimize returns to scarce cash, nutrient and labour resources.

5.2. Decision support tools as a research platform

The variable and complex biophysical and socio-economic conditions in smallholder farming systems in SSA dictate the need for decision support tools (DSTs) to improve understanding of crop-soil processes in time and space and provide insight into the suitability of technological options (Giller et al. 2006). Such tools provide a cost-effective and time saving approach to improve the diagnosis of constraints and opportunities in agricultural systems, the identification of options for alternative management, and analysing niches for scaling out (Bontkes and Wopereis 2003). Important DSTs that have significantly advanced understanding of characteristics and functioning of smallholder farming systems in SSA and the suitability of ISFM technologies include the DST to monitor nutrient balances at different spatial scales (NUTMON), various crop-soil simulation models, platforms for integrating modelling tools at farm-scale, and the Nutrient Use in Animal and Cropping systems – Efficiencies and Scales (NUANCES) framework that focuses on farm-scale processes affecting feasibility and impact of ISFM options (Giller et al. 2006).

The NUTMON DST has been widely used in SSA to assess the effects of current farmer management practices and alternative resource management options on nutrient balances (Smaling and Fresco 1993). Participatory research techniques such as resource flow mapping, matrix ranking and trend analysis are used to obtain the perspective of farmers. Next to this, a quantitative analysis is carried out which generates indicators such as nutrient flows, nutrient balances, cash flows, gross margins and farm income. Qualitative and quantitative analyses are then used to improve or design new technologies which tackle soil fertility management problems and which can help to increase the financial performance of the farm. The NUTMON framework or its components have been implemented in research and development projects addressing soil fertility management across SSA (e.g., Zingore et al., 2007b) and have aided improved understanding of soil fertility variability and farmers' resource use strategies. Results from the various studies using NUTMON have shown large negative nutrient balances, but have also highlighted strong variation among farmers. Nutrient balances were invariably negative on farms where large areas were used for production of cereal crops for home consumption (e.g., Nkonya et al., 2005), while positive balances were observed on mixed farms where farmers used manure (e.g., Onduru et al., 2007) and for high value cash crops that received large additions of nutrients (e.g., De Jager et al., 1998). Important considerations for 'local adaptation' of ISFM technologies that have been raised on the basis of the NUTMON approach include erosion control mechanisms to stem important nutrient losses, and use of participatory approaches to match technological options to farmers' objectives and socio-economic constraints, including labour.

The development and application of simulation models has aided exploration of the interaction between climatic and nutrient and crop management practices under smallholder farm conditions (Whitbread et al. 2010). Inter- and intra-seasonal ~~seasonal~~ rainfall variability is a major challenge for sustaining high crop productivity, with increasing occurrence of mid-season droughts; hence the important need for the development of flexible ISFM technologies that optimize crop productivity in good seasons and minimize losses in poor seasons. The Agricultural Production Systems sIMulator (APSIM) model has been widely applied to explore management strategies to minimize the climate risk associated with N fertilizer use by smallholder farmers (Whitbread et al., 2009). The model also proved useful in facilitating interactions between researchers and farmers in assessing fertilizer management strategies and effects of trade-offs between fertilizer and weed management on crop productivity (Dimes et al., 2002).

Despite the contributions of NUTMON and crop-soil models to improve local adaptation of ISFM technologies, there have been limitations in up-scaling their application at the farm level to explicitly integrate factors that drive farmers' decision making processes, including the variable nature of soil fertility within farms, sizes of different plots on the farms, mineral and organic resources available to farmers and other socio-economic constraints. To address this limitation, Thornton and Herrero (2001) developed a modelling framework that combines crop-soil and livestock models and a farm level database, allowing integration of soil, crop, livestock and socio-economic factors such as landholdings, household food sufficiency and labour in assessing the suitability of technological options for achieving food security and/or market production objectives on farms varying in resource endowment. The strength of integrating component models at the farm level is the analysis of trade-offs between resource use options considering soil fertility, crop productivity, livestock productivity, as well as, the objectives of the household. Zingore et al. (2008) used the integrated modelling approach to assess strategies for improving resource use in integrated crop-livestock systems in sub-humid areas in Kenya and Zimbabwe. The study highlighted the critical role of ISFM in sustainability of smallholder agriculture; as cropping was only sustainable on large farms (> 0.5 ha) with cattle and used fertilizer in combination with manure.

The ~~Nutrient Use in Animal and Cropping systems – Efficiencies and Scales (~~NUANCES~~)~~ framework aims at evaluating the short- and long-term impact of alternative farm-level management practices, with a special focus on trade-offs, using various system-analytical tools, including farm typologies, data-mining, participatory experimentation, and modelling. This ultimately leads towards the identification of opportunities and pathways towards the sustainable intensification of smallholder farming systems (Giller et al., 2011). The NUANCES framework provides a step-wise process to 'Describe' current production systems and their constraints, 'Explain' the consequences of current farmers' decisions on resource allocation, 'Explore' options for agro-technological improvement for a range of possible future scenarios, and 'Design', together with ~~the~~ farmers, new management systems that improve~~ments in~~ resource use efficiency and agricultural productivity ('DEED'). The NUANCES framework has been used to explore the potential of best-fit technologies and the ways they can be best combined at farm level for wide-ranging smallholder farming systems in SSA.

5.3. Moving decision support tools to farming communities

While above DSTs were mainly used as a platform for research to improve understanding of the complexity of smallholder farming systems, there is increasing scope for their use in guiding ISFM research to be accessible to farming communities. The International Plant Nutrition Institute has developed the Nutrient Expert (NE) extension support tool, a robust computer-based decision support tool that enables local experts to strategically formulate nutrient management guidelines for a range of crops and cropping systems (Pampolino et al., 2012). NE provides farmers with best nutrient management practices to attain a yield goal, that's aligned to a specific location, based on potential yield, attainable yield with best nutrient management, and farmer’s production objectives. Beyond recommendations for fertilizer and manure application, NE supports local adaptation by providing guidelines on liming and micronutrient requirements, and matching recommendations to available organic resources and fertilizer types available on the local market. NE also includes a profit analysis component to evaluate the costs and benefits of current and recommended, alternative practices. Lastly, as a learning tool for extension staff, NE adds value in moving from general recommendations to site-specific nutrient recommendations, adapted to production conditions and farmer’s objectives~~.~~ that are consistent with the scientific principles of Site-Specific Nutrient Management, which promotes the best practices of mineral and organic nutrient resources covering the right source, right rate, right time, and right place of nutrient application (Zingore and Johnston, 2013; Witt et al., 2009).

An example for application of NE to develop site-specific fertilizer recommendations for maize production in Western Kenya is presented in Table 7. Nutrient Expert algorithms to determine N, P, and K fertilizer requirements under specific field conditions were generated from on-farm multi-location nutrient omission trials data on the relationship between the balanced uptake of nutrients at harvest and grain yield, the soil’s nutrient supply potential and attainable yields, which varied depending on site-specific soil constraints. Under current management, maize yields under farmer management practices ranged from 1.4 to 4.4 t ha^{-1} in field types classified as having low to high soil fertility status (Table 7). Agronomic efficiencies of N under farmer practices were less than 22 kg grain kg^{-1} N, indicating suboptimal N responses for the yield range. Nutrient Expert recommendations showed large potential to increase yields under low and medium soil fertility conditions by at least 100%, while concomitantly increasing agronomic N efficiency to at least 25 kg grain kg^{-1} N (Table 7). Nutrient Expert showed a contrasting trend in recommendations for the high fertility field type by recommending reduction of N and P and including K – fertilizer recommendation targeted at ‘maintenance and balanced fertilization’ in nutrient-rich soils. Expected yield increases over current management were small, but high AE was achieved by avoiding oversupply of N and balanced nutrient application. A broad community of research and development organisations are working together through the African Soil Health Consortium (http://www.cabi.org/ashc/) to translate findings from research on ISFM. A series of handbooks, videos, posters, leaflets and policy briefs are being produced to support learning on ISFM for farmers, development organisations and at ~~tertiary~~ university level (e.g., Wairegi et al., 2014).

6. Conclusions and key research challenges

Koffi Annan, the chairman of the board of AGRA, stressed that the African Green Revolution should be uniquely African by recognizing the continent's great diversity of landscapes, soils, climates, cultures, and economic status, while also learning lessons from earlier Green Revolutions in Latin America and Asia (Annan, 2008). The 'local adaptation' component of ISFM is aligned to this request and operates at 2 scales: (i) at plot scale dealing with alleviating plot-specific constraints to enhanced fertilizer nutrient AE that are not sufficiently addressed by the introduction of improved germplasm and the application of organic inputs and (ii) at farm scale dealing with decision-making processes on allocation of resources (inputs, labour, etc) within the farm as affected by household production objectives and resource endowments.

At plot level, organic inputs alone, depending on their quality and quantity applied, can only alleviate some of the constraints that inhibit enhanced AE values for fertilizer (Table 1). Integration of other plot-level interventions has the potential to increase fertilizer nutrient AE values, and some of these interactions are well understood (e.g., the application of SMNs in combination with 'standard' fertilizer). The mechanistic basis for other interactions is less well developed. For instance, how do tillage operations affect fertilizer nutrient AE? Reduced tillage with retention of mulch can favour fertilizer AE through enhanced availability of soil moisture, especially under drought stress, but on the other hand, more continuous soil pore systems could favour movement of fertilizer nutrients to the subsoil. Lime application can enhance fertilizer AE by removing exchangeable Al constraints to crop growth but can change~~s~~ the soil chemistry and the relative availability of plant nutrients other than macronutrients. Furthermore, the diagnosis and rehabilitation, if feasible at all in economic and/or agronomic terms, of non-responsive soils is an important research topic, especially in areas where population densities are high with agricultural land in short supply. The impact of enhanced crop uptake of fertilizer on the overall soil fertility status with a specific emphasis on the soil organic C pool, is another topic that requires a better understanding since hypotheses can be formulated in relation to a decline in soil C due to enhanced nutrient availability or an increase in soil C due to the higher inputs of organic matter with increased crop productivity.

An important dimension for developing appropriate plot-level recommendations is the proper diagnosis of soil fertility-related constraints, especially in the context of highly variable soil fertility conditions in African smallholder agriculture. ‘Traditional’ laboratory approaches are costly and time-consuming and while spectroscopic approaches have demonstrated substantial progress in recent years, ultimately, indirect approaches, e.g., based on local soil fertility evaluation schemes, are likely to be important diagnostic tools.

Mapping secondary and micronutrient deficiencies on a national scale is useful for identifying large areas of likely deficiencies. Recently develop soil mapping approaches used the Africa Soil Information Services (AfSIS) project including compilation of existing soil survey information, data generation using infrared spectrometry, geo-spatial statistical analysis and remote sensing have enabled the rapid and cost effective development digital soil maps (http://africasoils.net/). This has offered opportunities to accelerate data collections for accurate diagnosis of soil fertility constraints and improve targeting of technological options. This needs to be followed by omission trials to determine crop-specific response to nutrient combinations and to assess the economics of incorporating secondary and micronutrients into NPK fertilizers at both regional and individual farm scales. While for some crops, e.g., maize, substantial efforts have been made to gather above information, other crops, e.g., cassava, bananas, or yams, have not received the attention required to intensify their production.

At farm scale, a better understanding of the interactions between soil fertility conditions, crop and land management practices, and yields as a basis for disentangling the often-observed large variability in responses to ISFM practices is necessary in order to develop household- and site-specific recommendations. Allocation of resources within heterogeneous farming communities and farms and its impact on overall farm productivity and resource use efficiency requires attention as does its interactions with household resource endowments and production objectives. Ultimately, ‘local adaptation’ interventions operate at the interplay of household decision-making processes and soil conditions (within ‘soilscapes’) and can only be fully developed and understood through interdisciplinary approaches, integrating expertise in soil fertility management, socio-economics, and social sciences~~, amongst other~~.

6. Acknowledgements

IITA wishes to acknowledge the various donors that have supported its Natural Resource Management research for development agenda for the past decades, through which the ISFM agenda was conceptualized and turned into action, and more specifically, the Bill and Melinda Gates Foundation (BMGF), the Directorate General for Development (Belgium), the International Fund for Agricultural Development (IFAD), and the United States Agency for International Development (USAID).

Table 1: A selected set of constraints that can prevent the uptake of nutrients applied with 'standard' fertilizer, or fertilizer that's commonly available and often composed of N, P, and/or K, and the potential of improved germplasm, organic resources and other amendments and/or soil management practices to alleviate these constrains.

Constraint	Potential of improved germplasm and organic resources and specific traits required	Other amendments or soil management practices
Soil acidity resulting in large amounts of exchangeable Al	Limited and short term – organic inputs with high decomposability, and preferably concentrated around the planting hole	Application of lime (calcite or dolomite) depending on Ca:Mg ratios and target crops
Secondary nutrient deficiencies	Limited – high quality species are required to supply a sufficient amount of secondary nutrients; high quality manure may contain sufficient secondary nutrients	Application of multi-nutrient fertilizer
Drought stress	Limited – Surface mulch with low quality (e.g., high lignin content and C-to-N ratio) can reduce evaporation and enhance soil moisture availability	Water harvesting techniques (e.g., zaï, tied ridges) can substantially increase water available for crops
Hard pan formation	Limited – Some deep-rooting trees or grasses may facilitate crop root growth	Deep tillage
Surface sealing	Appropriate – Surface mulch inhibits the formation of surface sealing	Surface tillage
Striga hermonthica damage	Appropriate – Use of crops triggering suicidal germination of Striga, surface mulch reduces Striga emergence	Use of Striga-tolerant/resistant varieties in combination with integrate Striga management options

Table 2: Cereal yield response in various African countries due to secondary and micronutrient additions.

Source: IFDC (unpublished).

~~Crop~~	~~Country~~	~~Number of sites~~	~~NP(K) only~~	~~NP(K) with secondary/ micronutrients~~	~~% yield increase~~	~~Additional nutrients~~

~~[1] Dolomite contributes both Ca and Mg, in addition to reducing soil acidity~~

Crop	Country	Number of sites	Yield with NP(K) only	Yield with NP(K) and with secondary/ micronutrients	Yield increase ±95% confidence interval	Additional nutrients
			---------------------------- t ha^{-1}	---------------------------		
Maize	Ethiopia	9	5.60	6.72	1.12±0.84	S, Zn, B
Wheat	Ethiopia	43	3.99	5.28	1.29±0.25	S, Zn, B, Cu
Maize	Burundi	44	3.11	5.27	2.16±0.29	Dolomite[1], S, Zn, B, Cu
Rice	Burundi	168	4.89	6.89	2.00±0.12	S, Zn, B, Cu
Maize	Mozambique	17	2.99	4.18	1.19±0.10	Mg, S, Zn, B
Wheat	Rwanda	40	4.14	5.64	1.50±0.25	K, S, Zn, B, Cu
Rice (paddy)	Rwanda	20	4.32	5.89	1.57±0.31	S, Zn, B, Cu

[1] Dolomite contributes both Ca and Mg, in addition to reducing soil acidity

Table 3: Agronomic efficiency of fertilizer N applied in treatments with tillage, zero-tillage without residue applied and zero tillage with residue applied. At each location and season the trials were carried out in 4 or 5 sub-locations and replicated 4 times for each sub-location. In Malawi and Mozambique land preparation in the tillage treatments was by hand hoe and in Zimbabwe and Zambia land was prepared using the mouldboard plough. Planting was done using the dibble stick and residue was applied in rates of 2.5 to 3 t ha^{-1}. Adapted from Thierfelder et al. (2013).

Country	Location and season	N fertilizer Agronomic Efficiency		
		With tillage	Zero-tillage	Zero-tillage with residue retention
		kg grain kg^{-1} fertilizer N

[1] It is assumed that HRE, MRE and LRE farms have manure in varying quantities of 10, 5 and 0 t of manure respectively, which is related to herd sizes. All farms have an equal total of 100 kg of N and 20 kg of P in the form of mineral fertilizers, meant to represent effects of an equal subsidy scheme. In the optimal allocation scenario, the nutrient resources are applied to fields where the highest agronomic efficiency can be achieved, based on Figure 3, and by avoiding over-supply of nutrients. The blanket recommendation consists of spreading manure and applying 10 kg P ha^{-1} and 30 kg N ha^{-1}, a typical recommendation by extension services. In some cases the blanket recommendation exceeds the total fertilizer amount at farmers' disposal.

Table 7: Maize productivity and N agronomic efficiency on the basis of fertilizer recommendations generated by Nutrient Expert. Maize yield response functions used to generate improved fertilizer recommendations were based on multi-location nutrient omission trials conducted on farms in different resource groups. Wide-ranging fields were simplified into three categories of soil fertility based on baseline yields and yield response to N, P and K fertilizer application.

Soil fertility status	Fertilizer N:P:K application rate	Maize productivity	Agronomic efficiency of N[1]
	kg ha^{-1}	t ha^{-1}	kg grain kg N^{-1}
	Current practice		
Low	21-3-0	1.4	19
Medium	32-9-0	2.2	21
High	80-58-0	4.4	18
	Nutrient Expert Recommendation		
Low	100-25-15	3.5	25
Medium	100-40-25	4.5	30
High	50-33-20	5.0	40

[1] Agronomic efficiency values were determined at variable P and K application rates, which may result in underestimation of agronomic N efficiency values in some cases. It is assumed that N is the most limiting nutrient and increasing P and K application at the rates of N considered will have small effects on agronomic N efficiency.

List of figures

Figure 1: Conceptual relationship between the agronomic efficiency (*AE*) of fertilizers and organic resource and the implementation of various components of ISFM, culminating in complete ISFM towards the right side of the graph. Soils that are responsive to NPK-based fertilizer and those that are poor and less-responsive are distinguished. The ‘current practice’ step assumes the use of the current average fertilizer application rate in SSA of 8 kg fertilizer nutrients ha^{-1}. Path ‘A’ indicates anticipated increases in AE when fertilizer is applied using appropriate agronomic practices in combination with adapted germplasm. Paths ‘B’ and ‘C’ refer to the need for addressing non-responsiveness (‘C’) before increases in AE can be expected on non-responsive soils, even after application fertilizer in combination with adapted germplasm (‘B’). Source: Vanlauwe et al. (2010).

Figure 2: High resource endowed farms (HRE) tend to have more cattle and manure and can maintain good soil fertility and crop yields across all of their fields. Low resource endowed farms (LRE) have no livestock and manure and their fields are often uniformly poor in soil fertility and crop yields. Farmers of intermediate resource endowment (MRE) have limited resources that they apply preferentially to the home fields creating strong gradients of soil fertility. This allows us to classify fields across the different farms into three types: fertile home fields, moderately fertile middle fields and poorly fertile outfields for three farmer typologies (HRE, MRE, and LRE) (cf. Zingore et al., 2007a).

Figure 3: Simulated crop yield with the model FIELD in function of mineral N application rates for different soil fertility zones on sand (a) and clay (b) soils and nutrient management options (only mineral N, manure at 10 t ha^{-1} and mineral N, mineral P at 20 kg ha^{-1} and mineral N) (refer to Zingore et al. (2011) for a detailed soil characterization and description of the FIELD model).

Figure 4: Revised conceptual framework underlying Integrated Soil Fertility Management (ISFM), adapted from the original version, presented by Vanlauwe et al. (2010). The current version distinguished plot from farm-level ‘local adaptation’ interventions.

Figure 5: Agronomic efficiency of P fertilizer in presence or absence of lime application, expressed as extra kg grain harvested per kg P ~~applied in~~ fertilizer~~s~~ (or extra kg fresh pods per ~~/~~kg P fertilizer in case of French beans). Data are adapted from case studies conducted in Kenya (Barasa et al., 2013; Gudu et al., 2005; Mbakaya et al., 2011), Cameroon (The et al., 2006), Burundi (ISABU, unpublished; IFDC, PAN-PSNEB project), and Ethiopia (Legesse et al., 2013).

Figure 6: Maize yield response to omission of various secondary and micronutrients in Burundi (average of 16 sites). An ‘ALL’ treatment consists of all likely deficient nutrients and included (per hectare) 750 kg dolomite (Ca+Mg lime), 71 kg N, 46 kg P_2O_5, 30 kg K_2O, 10 kg S, 3 kg Zn, 1 kg B (all soil-applied) and 0.25 kg Cu (applied as a foliar spray). Each subsequent treatment omits one nutrient. A decline in yield due to the omission of that nutrient indicates its relative contribution to yield. Error bars represent the 95% confidence interval on differences between omission treatments (ALL-dolomite, ALL-K, etc) and ALL treatment as determined by paired t-test. All differences are significant at the 5% level.

Figure 7: Conceptual relationships between fertilizer N application and grain yield, agronomic efficiency for nitrogen (N-AE) (a) and gross margin for different fertilizer:grain price ratios (b). ~~(~~Gross margins are calculated as: ~~=~~ grain yield (kg ha^{-1}) * grain price (USD kg^{-1}) – fertilizer N rate (kg ha^{-1}) * fertilizer cost (USD kg^{-1}).~~)~~Optimal fertilizer rates for maximum N-AE (diagonal arrows in Figure 7a) and gross margin (vertical arrows in Figure 7b) are indicated ~~with arrows~~ (based on Vanlauwe et al., 2011). ~~(Gross margin = yield*grain price – N rate*fertilizer cost)~~
