1 Supplementary Material

3 1. Calculations of the C, N and P inputs, and the N and P outputs and soil 4 system budgets in the Saria field experiment

5 The amounts of C, N, and P added with the manure were calculated using average values
6 derived from four studies (Arrivets, 1974; Sedogo, 1981; Bonzi, 2002; Kiba, 2012) (Table
7 S1). The manure was considered to have a water content of 20% at the time of application.
8 The amounts of C, N, P added by the seeds were calculated considering the recommended
9 seeding rates for sorghum and cowpea, and using 0.45 g C g^{-1} seed and the mean
10 concentrations of N and P in sorghum and cowpea seeds given in Kiba (2012) for the Saria
11 field experiment. Kiba (2012) estimated the proportion of N derived from the atmosphere in
12 cowpea (Ndfa shoot%) using the variations in natural abundance of ^{15}N in cowpea at
13 flowering and in neighbouring non-fixing plants measured as described in Oberson et al.
14 (2007). The amount of N derived from the atmosphere (Ndfa in shoot kg ha^{-1}) was calculated
15 by multiplying the Ndfa shoot% by the total amount of N taken up in the shoots (kg N ha^{-1}).
16 We considered that the Ndfa in root was 30% of the Ndfa in shoot as suggested by Adjei-
17 Nsiah et al. (2008). The total amount of C fixed in the soil/plant system was calculated using
18 the approach described in Bolinder et al. (2007). The shoot to root ratio of sorghum was
19 considered to be 14.7 (Pieri, 1989; Hien, 2004) which is close to the value of 11.6 published
20 by Bolinder et al. (2007) for North America. We used the average shoot to root ratio of
21 cowpea of 12.6 from Kimiti (2011) which is in agreement with the findings of Saidou et al.
22 (2012) for cowpea cultivars growing in a climatic zone comparable to Saria. We considered
23 the grain and shoot biomass produced by sorghum and cowpea between 1975 and 2010
24 (Table S2). All biomass data since 1975 were available except for 1980 when sorghum yield
25 was not measured and for 1993 and 2005 when the cowpea yield was not measured. The
26 straw biomass which was not measured in 1979 and 1995 for cowpea and in 2004 for
27 sorghum was estimated using the average harvest indices measured for each crop over the
28 entire study period. The variability of the cowpea and sorghum grain production with time is
29 shown in Figure S1. The N and P concentrations in shoot and grain were measured on
30 sorghum (2008 and 2010) and on cowpea (2009) by Kiba (2012) and considered to be
31 representative for the entire study period (1975 till 2010). The C content of shoot, grain and

32 root was considered to be 0.45 g g^{-1} as in Bolinder et al. (2007). The nutrient concentrations
 33 and the biomass data were used to calculate annual the amounts of N and P exported from the
 34 field in crop products (grain and straw). The amounts of N and P added through rainfall and
 35 dust from the Harmattan wind were calculated using the equations provided by Lesschen et
 36 al. (2007) considering an input of $300 \text{ kg dust ha}^{-1} \text{ year}^{-1}$. The following equations were used
 37 to calculate the different inputs:

$$38 \quad C_{\text{inputs}} = C_{\text{net photosynthesis}} + C_{\text{manure}} + C_{\text{seeds}} \quad (1)$$

$$39 \quad N_{\text{inputs}} =$$

$$40 \quad N_{\text{symbiotic fixation}} + N_{\text{manure}} + N_{\text{mineral fertilizer}} + N_{\text{rainfall}} + N_{\text{dust}} + N_{\text{seeds}} \quad (2)$$

$$41 \quad P_{\text{inputs}} = P_{\text{manure}} + P_{\text{mineral fertilizer}} + P_{\text{rainfall}} + P_{\text{dust}} + P_{\text{seeds}} \quad (3)$$

42

43 The N losses by leaching were set to $10 \text{ kg N ha}^{-1} \text{ year}^{-1}$ which is the order of magnitude
 44 given by Lesschen et al. (2007) and Bonzi (2002). The N losses by denitrification were
 45 calculated using the equation given by Lesschen et al. (2007). The N losses from the added
 46 urea were calculated using the results of Bonzi (2002) who used ^{15}N labelled urea to quantify
 47 the N losses. His results showed that 31% of the urea N was lost when added in the absence
 48 of manure, while 37% of the urea N was lost when added in the presence of manure. Most of
 49 these losses were due to volatilization. Since the slope of the field was limited, we assumed
 50 that losses through runoff and erosion could be neglected (Hien, 2004; Bonzi, 2002). No
 51 information was available on P losses to water. Lesschen et al. (2007) considered P leaching
 52 to be negligible but this was probably not correct in the MINFYM2 treatment. The following
 53 equations were used to calculate the different outputs:

$$54 \quad N_{\text{outputs}} = N_{\text{crop products (grain and straw)}} + N_{\text{atmosphere (N}_2\text{O} + \text{NH}_3)} + N_{\text{leaching}} \quad (4)$$

$$55 \quad P_{\text{outputs}} = P_{\text{crop products (grain and straw)}} \quad (5)$$

56 The N and P soil system budgets were calculated as follow:

$$57 \quad N_{\text{soil system budget}} = N_{\text{inputs}} - N_{\text{outputs}} \quad (6)$$

$$58 \quad P_{\text{soil system budget}} = P_{\text{inputs}} - P_{\text{outputs}} \quad (7)$$

60 **2. Soil, plant and manure analyses in the Saria field experiment**

61 Representative plant (grain and stover) and manure samples were taken in 2008, 2009 and
62 2010 and analysed for N with a CN analyser (Vario Pyro Cube, Elementar GmbH, Hanau
63 Germany). They were analysed for P after ashing at 550°C, solubilisation of ashes in
64 concentrated HCl and P analysis in colorimetry using malachite green (Ohno and Zibilske
65 1991). ¹⁵N in plant samples was measured using an isotope ratio mass spectrometer (Isoprime
66 100, Isoprime Ltd., Manchester UK) connected to the CN analyser.

67 Representative soil samples were taken during the dry season in 2009 and 2013 from the top
68 10 cm. Soil pH was measured in a 1:10 soil:water ratio. Total C and total N were measured
69 using a CN analyser. Total P was digested with H₂SO₄ and H₂O₂ (Anderson and Ingram,
70 1993) and analysed colorimetrically. The method of Saunders and Williams (1955) delivered
71 extremely low results and therefore total organic P (Po) was measured after a NaOH-EDTA
72 extraction as proposed by Bowman and Moir (1993). Microbial nutrients were quantified
73 after having incubated the soils in the absence of fresh residue addition at 60% of the water
74 holding capacity and 25°C for 2 weeks. Microbial C and N (Cchl, Nchl) were derived from
75 the difference in C and N measured in 0.5 M K₂SO₄ extracts of soil samples fumigated with
76 CHCl₃ or not as described by Vance et al. (1987). The C and N concentrations in the extracts
77 were measured with a Total Organic Carbon analyser TOC-L and with a Total Nitrogen
78 measuring unit TNM-L (Shimadzu, Kyoto, Japan). The total dissolved nitrogen (DN) of the
79 non-fumigated sample was taken as a proxy for soil mineral N. Microbial P (Phex) was
80 derived from the difference in resin extractable P of soil samples fumigated or not with
81 hexanol after Kouno et al. (1995). Resin extractable P was then measured colorimetrically.
82 Based on the recovery of an inorganic P spike, Phex was corrected for sorption of P released
83 from microbial cells during extraction. We corrected for incomplete microbial C, N and P
84 extractions by using the k_C, k_N, and k_P factors mentioned in Table 1 (0.45 for C and N and 0.4
85 for P) in order to compare our results to those presented in this Table. The average values of
86 total P, C and N, organic P, resin extractable P and microbial C, N and P concentrations of
87 the replicates 2, 3, and 4 of the treatments CON, MIN1, MINFYM1 have been reported in
88 Traoré et al. (2015). The data on grain and straw biomass, nutrient concentration, nutrient
89 export and N₂ fixation by cowpea shoots have been reported in Kiba (2012).

90

91 **3. Calculations of the C, N and P input, N and P outputs, and C, N and P**
92 **soil system budgets in the Wagga Wagga field experiment**

93 Average wheat and lupin yields (grain and total dry matter) were calculated for the period
94 1979-2002. Concentrations of N and P in wheat and lupin grain and in wheat straw have not
95 been determined each year. Therefore, they were averaged across treatments and years to
96 calculate N and P outputs with grains, and the return of N and P to the soil with crop residues.
97 Since N concentrations in lupin straw were not available, we used a typical value of 9 g N kg⁻¹
98 ¹ in lupin straw at maturity (Ann McNeill, personal communication). Annual dry matter of
99 subterranean clover was not determined in the trial but we assumed an average of 7 t ha⁻¹
100 year⁻¹ (Murray Unkovich, personal communication). Total N₂ fixed in the shoots and roots
101 was taken from Unkovich et al. (2010) for a total shoot dry matter of 7 t ha⁻¹ for subterranean
102 clover and of 8 t ha⁻¹ for lupin. We considered recommended sowing densities for lupin,
103 wheat and subterranean clover for the region and the N and P concentrations of grain to
104 calculate the inputs of N and P with seed. The inputs of N and P by rainfall were taken from
105 McKee and Eyre (2000). The total C, N and P inputs were calculated with equations (1), (2),
106 and (3).

107 Given the difficulties of estimating the losses of C from the soil to the atmosphere we relied
108 on the results of Heenan et al. (2004) who measured and modelled the changes in soil organic
109 C and total N in the 0 to 10 cm horizon between 1979 and 2000 in the different treatments of
110 the trial. We used the slope of the linear change of C and N stocks (kg ha⁻¹) with time as an
111 estimate of the yearly C and N soil system budget in the 0-10 cm horizon. We compared the
112 N budget derived from Heenan et al. (2004) with the budget calculated in this study to check
113 the validity of our calculations.

114 The losses of N and P due to the export of wheat and lupin grains were calculated knowing
115 the biomass produced and the nutrient concentration. The losses of N due to stubble burning
116 were estimated to be 100% in burnt wheat straw and 30% in burnt lupin straw, which drops
117 leaves early and does not burn completely (Heenan et al., 2004). Bünemann et al. (2006)
118 estimated the losses of P due to burning to be 50% in wheat straw and 15% in lupin straw, as
119 a fraction of the P was returned to the soil as ashes, while the rest was transported away as
120 dust. In accordance with Heenan et al. (2004), losses of N and P by erosion and runoff were

121 considered to be negligible due to the limited slope (less than 2%) and the good drainage of
122 the site. N losses by leaching and to the atmosphere were also probably very low in this
123 grazed system as no N fertilizer was added (Murray Unkovich and Guangdi Li, personal
124 communications). We considered a total annual N loss of 15 kg ha⁻¹ year which is on the
125 lower side of the N losses by leaching reported by Ridley et al. (2004) for legume based
126 grazed systems in Southern Australia, and no P loss (Warwick Dougherty, personal
127 communication). The total N and P outputs and budgets were calculated with equations (4),
128 (5), (6) and (7) including the outputs related to burning.

129 The soil data shown here originates from Bünemann et al. (2006) and Bünemann et al.
130 (2008). Samples were taken in 2005 from 0-5 cm in blocks 1, 3 and 5. We considered in this
131 work the total organic P measured by the method of Saunders and Williams (1955).

132

133 **4. Calculations of the C, N and P input, N and P outputs, and C, N and P** 134 **soil system budgets in the DOK field experiment**

135 The amounts of N and P added as mineral fertilizers and manure and exported in plant
136 products were recorded for the entire duration of the experiment by Agroscope, based on
137 elemental analyses of manures and plant products. The average annual inputs with fertilizer
138 and manure between 1978 and 2006 were reported in Oberson et al. (2013), except for MIN.
139 However, we include in the present work the period 1978 to 1991 when MIN was not
140 fertilized, a period which was excluded in Oberson et al. (2013). The amounts of N and P
141 added by seeds were calculated from the average sowing/planting density and the N and P
142 concentration of seeds or planting material (Flisch et al., 2009). The annual N inputs by N₂
143 fixation in the shoots of white and red clover in the grass-clover leys, and the proportion of
144 grass N derived from the clover during the second year of ley phase have been reported by
145 Oberson et al. (2013) based on a two-year study. The amount of N fixed from the atmosphere
146 contained in the clover roots was calculated considering that shoots and roots had the same
147 %Ndfa and a shoot to root N ratio of 2.46 as proposed by Unkovich et al. (2010) for annual
148 pasture legume species. Since the ley phases lasted either 2 or 3 years, we proceeded as
149 follows: the annual N fixation in clover shoots reported in Oberson et al. (2013) for 2007 was
150 multiplied with the number of years of ley phase. The yields obtained in 2007 were in the
151 range of grass-clover yields reported for the entire duration of the DOK field experiment

152 (Gunst et al., 2007), and the grass-clover yields of treatments MIN, ORG and MINORG
153 remained fairly stable between 1978 and 2005 (Gunst et al., 2007). Likewise, the clover
154 proportions reported by Oberson et al. (2013) agreed with proportions reported earlier for the
155 DOK field experiment (Besson et al., 1992). Further, we assumed that the N transfer to the
156 grass would still be negligible during the first year of ley (<5% to around 20% of grass N
157 derived from legume N, Oberson et al., 2013) and included it only in the 2nd on 3rd year of ley
158 phase, when on average 53% of grass N was derived from clover. Finally, we calculated the
159 root N in relation to the fixed N amount accumulated in clover during one year, irrespective
160 whether the ley phase lasted two or three years. Doing so, we account for the uncertainties in
161 those estimates (Unkovich et al., 2010) and for the fact that legume N was transferred to
162 grass. The annual N inputs by N₂ fixation in the shoots of soybean have been reported by
163 Oberson et al. (2007). We revised them, using the treatment specific average soybean yields
164 reported by Jossi et al. (2009), since the yields determined in microplots installed in plots of
165 the DOK experiment (Oberson et al., 2007) significantly exceeded the yields obtained on the
166 entire field plot. We added to the amounts of fixed N in the shoots the amount of fixed N₂
167 contained in the roots using the shoot to root N ratio of 1.63 proposed for soybean by
168 Unkovich et al. (2010) and the same Ndfa in % as in the shoots. The average annual input by
169 symbiotic fixation was calculated for each rotation period (*i. e.*, considering the type and
170 duration of legume crop included) and averaged for the entire duration from 1978 till 2006.
171 The annual inputs by wet and dry depositions were taken from Bosshard (2007) for N and
172 from Spiess (2011) for P. The total N and P inputs were calculated with equations (2) and (3).

173 The annual C inputs and the changes in soil organic C stocks were quantified for each
174 treatment by Leifeld et al. (2009) for the 0 to 20 cm horizon between 1979 and 2004. As it
175 was difficult to obtain reliable information on the losses of soil C, we did not estimate the
176 total C outputs from the different treatments. Instead, an estimate of the yearly C budget in
177 the 0-20 cm soil layer could be derived from the slope of the linear change of soil C stocks
178 with time (kg ha⁻¹ year⁻¹) reported by Leifeld et al. (2009).

179 The total N and P outputs from the soil/plant system were calculated as the sum of N and P
180 exported by agricultural products and of N and P losses to the environment (water,
181 atmosphere and deep soil horizons). We used the average annual exports by products from
182 1978 and 2006 from Oberson et al. (2013), including for MIN the period from 1978 to 1991
183 when MIN was not fertilized. The losses of N from the added fertilizers were calculated from

184 the study of Bosshard et al. (2009) who studied the fate of ^{15}N labelled manure and mineral
185 fertilizer added to the MIN and ORG treatment over a period of 3 years. The amount of N
186 fertilizer lost to the environment was calculated from the amount of ^{15}N that could not be
187 recovered in the soil/plant system (considering a soil depth of 50 cm) over a period of 3
188 years. Since MINORG received as much manure as ORG we considered that both treatments
189 lost the same amount of N from the fertilizer to the environment. Nitrogen can also be lost
190 from soil N reserves and not only from added N fertilizers. Since no information was
191 available on the amount of N lost from native soil stocks to the environment (atmosphere,
192 deep soil horizons, water), we estimated it as follows. We considered the concentrations of
193 soil total N given in Bosshard (2007) for the layers 0-20 and 30-50 cm sampled in 1977, and
194 the concentration of soil N measured by Oberson et al. (2013) in the 0-20 cm layer of the
195 NON treatment. From these data we estimated the stocks of N present in the first 50 cm in
196 1977 and in 2006. The amount of N lost from the native stock of organic matter present in the
197 first 50 cm of the NON treatment was calculated as the stock evaluated for 1977 minus the
198 stock evaluated for 2006 plus the sum of N inputs (by atmospheric depositions, symbiotic
199 fixation and the seeds) minus the exportations by crops. This yielded a loss of 10 kg N ha^{-1}
200 year^{-1} which was considered to be additive to N lost from the added fertilizers. The calculated
201 N budget (sum of inputs – sum of outputs) was compared to the change in total soil N
202 calculated independently by Bosshard (2007) for the 0-50 cm soil layer in the treatments MIN
203 and ORG over the first 26 years of the DOK field experiment for a plausibility check. The P
204 losses to the environment were not measured in this experiment. We used the P losses
205 calculated by Prasuhn et al. (2004) for another cultivated area of northern Switzerland
206 including similar soils and cropping systems. The total N and P outputs and budgets were
207 calculated with equations (4), (5), (6) and (7).

208 The following soil analyses were conducted on soil sampled between 2004 and 2009 taken
209 from the 0 to 20 cm soil layer in plots of rotation unit c or b, or both. The pH, total C and
210 total N (soil sampled in 2006) have been published in Oberson et al. (2013). Other soil data
211 have not yet been published. Anion exchange resin extractable P (as an indicator for available
212 P) and microbial P were measured on soil samples taken in 2009, and microbial C, N on soil
213 samples taken in 2004, using the methods described in section 2 of the supplementary
214 materials. Organic P and total P were determined as described by Saunders and Williams
215 (1955), on soil sampled in 2005. Total soil P content was measured on soil ashed at 550°C

216 and extracted with 0.5 M H₂SO₄. Mineral N was the sum of N-NO₃ and N-NH₄ extracted
217 with 1 M KCl and measured colorimetrically (soil sampled in 2004).

218

219 **5. Statistics**

220 Treatment effects on soil parameters were tested using ANOVA of the statistical analysis
221 package SYSTAT 12 (Systat Software Inc., Chicago, USA) Molar ratios were log
222 transformed prior to analysis, to meet the requirements of ANOVA. Likewise, nutrient
223 concentrations were log transformed if Shapiro-Wilk (normal distribution) and/or Levene
224 (equality of variances) tests suggested that assumptions of ANOVA were not met. Data of all
225 field experiments underwent these same procedures, except that the block factor was always
226 considered in the analysis of the Wagga Wagga trial (in agreement with Bünemann et al.,
227 2006).
