14 15 **Abstract**

16 Uncertainties concerning stabilization of organic compounds in soil limit our basic
17 understanding on soil organic matter (SOM) formation and our ability to model and manage
18 effects of global change on SOM stocks. One controversially debated aspect is the
19 contribution of aromatic litter components, such as lignin and tannins, to stable SOM forms.
20 In the present opinion paper, we summarize and discuss the inconsistencies and propose
21 research options to clear them.

22 Lignin degradation takes place step-wise, starting with (i) depolymerisation, followed by (ii)
23 transformation of the water-soluble depolymerization products. The long-term fate of the
24 depolymerization products and other soluble aromatics, e.g., tannins, in the mineral soils is
25 still a mystery. Research on dissolved organic matter (DOM) composition and fluxes
26 indicates dissolved aromatics are important precursors of stable SOM attached to mineral
27 surfaces and persist in soils for centuries to millennia. Evidence comes from flux analyses in
28 soil profiles, biodegradation assays, and sorption experiments. In contrast, studies on
29 composition of mineral-associated SOM indicate the prevalence of non-aromatic microbial-

1 derived compounds. Other studies suggest the turnover of lignin in soil can be faster than the
2 turnover of bulk SOM. Mechanisms that can explain the apparent fast disappearance of lignin
3 in mineral soils are, however, not yet identified.

4 The contradictions might be explained by analytical problems. Commonly used methods
5 probably detect only a fraction of the aromatics stored in the mineral soil. Careful data
6 interpretation, critical assessment of analytical limitations, and combined studies on DOM
7 and solid-phase SOM could thus be ways to unveil the issues.

8

9 **1 Introduction**

10 Storage and quality of soil organic matter (SOM) determine many crucial soil properties and
11 the cycles of carbon (C) and essential nutrients through ecosystems. The storage of SOM is
12 determined by plant litter inputs and decomposition processes. Decomposition of SOM is a
13 significant source of atmospheric CO₂, thus, a critical parameter in climate models
14 (Schlesinger and Andrews, 2000). Decomposition rates are sensitive to global change factors
15 such as temperature, precipitation, and land use. However, our ability to understand and
16 predict such responses is limited by uncertainties about pathways of organic matter
17 transformation in soil. In particular, the question as to why some SOM components persist in
18 soil for centuries (denoted as `stable SOM` from here on) while others turn over quickly is
19 still puzzling (Schmidt et al., 2011).

20 Recent research challenges traditional theories presuming that stable SOM results from
21 neoformation of complex humic polymers in soil (`humification`). Stable SOM rather seems
22 to be composed of relatively simple organic compounds that are protected against
23 biodegradation, e.g., because they are tightly bound to mineral surfaces (Schmidt et al., 2011;
24 Kleber et al., 2015). Herein, we hold to this view but argue that, despite extensive research in
25 the last years, the chemistry and source of compounds incorporated into stable SOM is still
26 largely uncertain. In particular, the importance of aromatic compounds derived from abundant
27 plant litter components, such as lignin and tannins, is controversially debated (Figure 1). One
28 line of evidence suggests that they are important contributors to stable SOM. It bases
29 primarily on data from research on fluxes and behaviour of dissolved organic matter (DOM)
30 in soil, hence, we will denote it as the `dissolved phase line of evidence`. A contrasting line of
31 evidence suggests a quick degradation of aromatic compounds in soil derives primarily from
32 analyses of the composition of solid SOM (`solid phase line of evidence`). Herein, we sum up

1 and confront the arguments of the two views, discuss potential reasons for the controversies
2 (including limitations in analytical methods and process understanding) as well as their
3 implications for our basic understanding on SOM formation.

4

5 **2 Dissolved phase line of evidence**

6 The view that plant-derived aromatics are a major source of stable SOM is based on the
7 following two main arguments:

8 (1) DOM produced during litter decomposition and leached into mineral soil is a main
9 source of stable SOM adsorbed on mineral surfaces.

10 (2) Aromatic DOM components produced during litter decomposition are resistant to
11 mineralization and preferentially sorb to mineral surfaces. Hence, they are
12 preferentially stabilized in mineral soil.

13

14 **2.1 Argument 1: DOM as source of stable SOM**

15 Leaching of DOM is a major pathway for organic matter translocation from forest floor into
16 the topsoil horizons. Estimates for acidic forest soils with permanent forest floor suggest that
17 25-89% of the SOM stored in mineral soils derives from DOM (Neff and Asner, 2001;
18 Michalzik et al., 2003; Kalbitz and Kaiser, 2008), based on the typical observation of
19 decreasing DOC fluxes with depth of the mineral soil (a large compilation of data from
20 studies on forest and grassland soils is presented by Neff and Asner, 2001). Two processes
21 can explain the decrease: mineralization and sorption.

22 Sorption of DOM to mineral surfaces likely is a major process forming stable SOM in many
23 soils. Evidence for its importance comes from findings that the turnover and storage of SOM
24 in mineral soil horizons is often related to the contents of reactive secondary minerals (e.g., Fe
25 hydrous oxides, short-range ordered Al hydroxides). Such relationships have been found
26 across a wide range of soil types (Kramer et al., 2012; Kleber et al., 2015). Also, higher
27 radiocarbon age of SOM in heavy (i.e., mineral) fractions compared to light density (i.e.
28 organic) fractions indicates that sorption stabilizes organic compounds (e.g., Marschner et al.,
29 2008, Kleber et al., 2015). Density fractionation procedures indicate that the total soil C

1 associated with minerals in any given location can vary from 30% to 90% (see data compiled
2 in Kleber et al., 2015). The relevance of sorptive stabilization depends on soil properties. Low
3 soil pH enhances the formation of reactive secondary minerals and favors the formation of
4 strong bonds between organic matter and the mineral surface (Kleber et al., 2015). Most
5 studies cited herein (for both lines of evidence) examined acidic soils under temperate forests,
6 in which sorptive stabilization clearly should play an important role.

7

8 **2.2 Argument 2: Preferential stabilization of aromatic DOM components**

9 Lignin, a macromolecule composed of phenyl propane units, is a major plant cell wall
10 component (Kögel-Knabner, 2002). Typically, lignin concentrations negatively correlate with
11 litter decomposition rates. They are the predominant control on litter decomposition within
12 biomes worldwide (Cornwell et al., 2008), indicating that the lignin macromolecule is among
13 the most persistent litter constituents. Nevertheless, results of recent studies suggest
14 significant chemical alteration and losses of lignin already within the first months of litter
15 decomposition (e.g., Preston et al., 2009; Klotzbücher et al., 2011). 'Degradation' of lignin
16 has to be considered a step-wise process: (i) the first step is the depolymerization of the
17 macromolecule, releasing (mainly aromatic) water-soluble depolymerisation products of
18 varying molecular weight; (ii) these products can then be further transformed, and low-
19 molecular weight compounds are eventually taken up by microorganisms to produce biomass
20 or CO₂. Hence, losses of lignin-derived C during litter decomposition can occur due to
21 leaching of water-soluble products of an incomplete degradation or as CO₂. Laboratory
22 incubation tests on water-extractable organic matter from various forest floor materials
23 suggest that aromatic components are more resistant to mineralization than non-aromatic
24 components (Kalbitz et al., 2003 a,b; Hansson et al., 2010). This suggests that leaching is an
25 important factor in loss of lignin-derived matter during litter decomposition. Consistent with
26 this conceptual model, the typically high UV absorptivity of DOM leached from forest floors
27 is indicative of a large contribution of aromatic components (e.g., Kalbitz and Kaiser, 2008).

28 Another factor for the export of aromatic DOM from forest floors is leaching of tannins.
29 Tannins are water-soluble polyphenols of a molecular weight ranging from 500 to 3000
30 Daltons. Tannins rapidly leach from fresh litter; most studies suggest losses of ~80% within
31 the first year of litter decomposition (Kraus et al., 2003).

1 It has been commonly found that the contribution of components likely derived from lignin
2 and tannins to DOM decreases with depth of the mineral soil (summarized in Table 1), i.e.,
3 the decrease in fluxes of these compounds with depth is more pronounced than the decrease
4 of bulk DOM. One explanation might be intensive biodegradation of aromatics in mineral
5 soil. However, this would contradict results of the DOM biodegradation studies previously
6 discussed. Hence, a more likely explanation is sorption to mineral surfaces. Laboratory
7 sorption experiments support this view; a typical observation is that lignin-derived aromatic
8 DOM components are preferentially sorbed by minerals and soils (e.g., Kaiser et al., 1996;
9 Chorover and Amistadi, 2001; Hunt et al., 2007), and for some soils it has been shown they
10 displace previously bound organic components from mineral surfaces (e.g., Kaiser et al.,
11 1996). The degree of preferential sorption may depend on the composition of the soil mineral
12 assemblage. Chorover and Amistadi (2001) observed that high molecular weight aromatic
13 components preferentially sorbed onto goethite, while for montmorillonite no preference for
14 aromatic moieties was observed. A likely reason for the preferential sorption is the large
15 content of carboxyl groups linked to the aromatic rings, which bind to metals at mineral
16 surfaces via ligand exchange reactions.

17

18 **2.3. Roots as source of stabilized aromatic SOM?**

19 We have so far focused on DOM leached from aboveground litter. However, roots might also
20 be a crucial source of stable SOM. The contribution of root and aboveground litter as major
21 source of SOM has been debated in numerous studies, but the available information allows no
22 definite conclusions yet (see discussion in Lajtha et al., 2014). Presumably, the relative
23 importance of the two types of organic matter input for SOM storage in topsoils differs
24 between ecosystems (Crow et al., 2009) and the importance of root-derived matter increases
25 with soil profile depth (Rumpel et al., 2015).

26 This raises issue of whether results from aboveground litter decomposition would also apply
27 to root litter decomposition. Data by Crow et al. (2009) suggest that lignin concentrations of
28 roots are in the range of those of leaf and needle litter. Hansson et al. (2010) showed that
29 DOM production during root decomposition occurs in patterns that are similar to those of
30 needle decomposition. Particularly during later decomposition stages, root-derived DOM is
31 enriched in aromatics resistant to mineralization. Hence, available information suggests that
32 root decomposition is just another important source of soluble aromatics in mineral soils.

1 However, to the best of our knowledge, studies to quantify the contribution of root-derived
2 aromatics to DOM fluxes in the field have yet to be conducted.

3

4 **3 Solid phase line of evidence**

5 Many of the recent conceptual papers on SOM formation are built on the assumption that
6 lignin-derived aromatics disappear quickly in soil, while SOM in mineral soils is dominated
7 by non-aromatic and microbial-derived compounds (Grandy and Neff, 2008; Schmidt et al.,
8 2011; Dungait et al., 2012; Miltner et al., 2012; Cotrufo et al., 2013; Castellano et al., 2015).
9 Empirical support is provided by studies characterizing the chemical structure of solid SOM
10 using a variety of analytical methods. In the following, we sum up the most widely cited
11 work.

12 Numerous studies on a wide variety of soil types used the cupric oxide (CuO) method to
13 analyse the distribution of lignin-derived phenols in profiles. Most of them reported
14 decreasing phenol contribution to SOM from forest floor to A horizons and with depth of the
15 mineral soil (reviewed in Thevenot et al., 2010). Measured phenols also decreases with
16 increasing density of soil fractions, hence, are relatively small component in heavy (i.e.,
17 mineral-associated) and old soil fractions (e.g., Sollins et al., 2009; Kögel-Knabner et al.,
18 2008; Cerli et al., 2012). Similar results are reported by studies using pyrolysis-gas
19 chromatography/mass spectrometry (see e.g., data and references provided by Grandy and
20 Neff, 2008 and by Buurman et al., 2007) and tetramethylammonium hydroxide (TMAH)
21 thermochemolysis (Mason et al., 2012).

22 Analysis of heavy and clay-sized soil fractions using cross polarization and magic angle
23 spinning (CPMAS) ¹³C nuclear magnetic resonance spectroscopy (¹³C-NMR) typically finds
24 high peak intensities of alkyl and O/N alkyl C (mostly assigned to polysaccharides and
25 proteins) and low peak intensities of aryl C (mostly assigned to lignin and tannins) (see
26 reviews by Kögel-Knabner et al., 2008 and Miltner et al., 2012). In a comprehensive study on
27 Ah horizons from 8 European forest sites, O/N alkyl C contributed up to 41-49% of total peak
28 intensity in the <2- μ m fraction, and the peak intensities were on average 10% higher than the
29 those reported for bulk soil; the intensities of aryl C in the <2- μ m fraction contributed 13-15%
30 of total peak intensities, and they were on average 24% lower than values found for bulk soil
31 (Schöning et al., 2005). Consistent with findings, the heavy soil fraction is characterized by
32 low C/N values close to those of microbial tissues (Kögel-Knabner et al., 2008). Studies using

1 near-edge X-ray absorption fine structure (NEXAFS) spectra supported the conclusions
2 drawn from ¹³C-NMR analysis of a significant contribution of microbial-derived compounds
3 to SOM at mineral surfaces (Lehmann et al., 2007; Kleber et al., 2011).

4 Lignin turnover (i.e., transformation into CO₂ or non-lignin products) in temperate arable,
5 grassland, and tropical forest soils has been estimated using a combination of isotopic labeling
6 and compound-specific isotope analysis of lignin-derived aromatics applying the CuO
7 method. Most of the studies using this approach suggest that the turnover of lignin-derived
8 aromatics is faster than the turnover of bulk SOM (Dignac et al., 2005; Heim and Schmidt,
9 2007; Heim et al., 2010). A modelling study based on the data by Dignac et al. (2005)
10 suggested that about 90% of the lignin is mineralized as CO₂ or transformed into compounds
11 devoid of lignin-type signatures within one year (Rasse et al., 2006). However, a study by
12 Hofmann et al. (2009) suggests that after 18 years, approximately two-thirds of the initial
13 lignin phenols remained in an arable soil. The authors concluded that lignin was preferentially
14 preserved in the soil. It should be noted all of these land-use successional studies only
15 determined turnover times in the top 10-30cm of the soil horizon and may not accurately
16 represent lignin dynamics in the deeper soil.

18 **4 Reasons for the controversies**

20 **4.1. Analytical limitations**

21 The controversies in current literature might (partly) be due to difficulties in the analyses of
22 aromatic matter in soils. Studies on DOM typically use bulk methods for inferring aromatic
23 content, including UV absorbance and fluorescence spectroscopy. Limitations of this research
24 include lack of identification of the source of aromatic compounds, and poor quantification of
25 the fluxes. Also data on contribution of aromatic components to solid SOM are semi-
26 quantitative or qualitative.

27 Commonly applied methods such as CuO oxidation, pyrolysis or TMAH thermochemolysis
28 focus on few defined lignin-derived monomers to estimate the overall contribution of lignin.
29 These estimates, however, can largely differ depending on the method applied (Klotzbücher et
30 al., 2011). As outlined by Amelung et al. (2008), compound-specific isotope analysis of
31 lignin-derived compounds with the CuO method presumably overestimates the turnover rates

1 of lignin as only part of the lignin-derived aromatics can be extracted from soil (incomplete
2 extraction might also be a problem in all analyses of biomarkers, for which turnover times
3 typically are estimated to be faster than turnover rates of bulk SOM). Firstly, CuO oxidation
4 (as well as conventional pyrolysis or TMAH thermochemolysis) does not completely
5 depolymerize lignin (Johansson et al., 1986; Goñi and Hedges, 1992; Filley et al., 2000).
6 Secondly, lignin-derived aromatics bound to mineral surfaces are only partly assessed by the
7 CuO method (Hernes et al., 2013). Thirdly, lignin-derived aromatics might be altered in a way
8 that they escape the `analytical window` and cannot be ascribed to a lignin source anymore.
9 For instance, the CuO method yields a number of aromatic monomers of unknown origin
10 besides the lignin-derived monomers (Cerli et al., 2008). These compounds are typically not
11 quantified, and thus, not considered in estimates of the SOM composition. Hence, monomer
12 yield is a commonly used but uncertain measure of lignin concentration in soil. Our
13 knowledge about how much lignin is `hidden` (Hernes et al., 2013) in soil is still insufficient.

14 The uncertainties related to quantification of SOM compositions with solid-state CPMAS ¹³C-
15 NMR have been intensively discussed in the literature (see Knicker, 2011). Mineral soil
16 samples are commonly pretreated with hydrofluoric acid in order to remove paramagnetic
17 minerals that disturb the analysis. The treatment can result in significant losses of SOM, and
18 one might lose important information on SOM adsorbed onto minerals (e.g., SOM losses of
19 10-30% in topsoil samples and up to 90% in subsoil; Eusterhues et al., 2003). Further
20 uncertainties arise from signal overlapping and a low sensitivity for aromatic C in soils (e.g.,
21 Skjemstad et al., 1996; Mao et al., 2000; Simpson and Simpson, 2012). It has been shown that
22 the technique underestimates lignin vs. cellulose in ligno-cellulose isolated from wheat
23 (Gauthier et al., 2002). By applying Bloch decay, another type of ¹³C-NMR technique, one
24 can overcome the problem of the reduced sensitivity for aromatic-C. The technique has been
25 applied in studies on pyrogenic organic matter, for which CPMAS ¹³C-NMR should be even
26 less sensitive than for lignin as it is more condensed (Golchin et al., 1997; Simpson and
27 Hatcher, 2004; Knicker et al., 2005). Bloch decay is, however, not routinely applied in SOM
28 research as it is an extremely time-consuming experiment and the required instrument time is
29 frequently not available (Simpson and Hatcher, 2004).

30 Pyrogenic organic matter is an important source of aromatic compounds in many soils.
31 Despite extensive research efforts, rates and pathways of pyrogenic organic matter
32 decomposition are still not well established (Schmidt et al., 2011; Kuzyakov et al., 2014).

1 Analyses of benzenecarboxylic acids as molecular markers suggest that aromatic compounds
2 derived from pyrogenic organic matter are translocated within soil profiles and bind to
3 mineral surfaces (Haumaier, 2010). The quantitative contribution of pyrogenic organic matter
4 to DOM in soil is, however, still poorly studied (Smebye et al., 2016). Bulk analyses of
5 aromatic matter used in most research on DOM fluxes cannot distinguish if the compounds
6 derive from plant litter or from pyrogenic organic matter. This limits our understanding of the
7 processes controlling turnover of aromatics. If a significant part of aromatic DOM in mineral
8 soil derives from pyrogenic organic matter, the `loss` of plant litter-derived aromatics in
9 mineral soil would be even more pronounced. Problems distinguishing sources of aromatic
10 compounds can also occur in analysis of solid-phase SOM with CPMAS ¹³C-NMR analysis
11 (Simpson and Hatcher, 2004).

12

13 **4.2. Limits in process understanding**

14 Another source of uncertainty in quantifying the role of aromatics in SOM stabilization is that
15 the timescales of the different processes affecting aromatic compounds vary considerably.
16 Solubilization, leaching, and sorption of lignin-derived compounds might occur in a few days.
17 In contrast, the composition of SOM as well as the mineral assemblage in soils is the result of
18 years to centuries of biogeochemical processing. Possibly, one cannot simply extrapolate
19 from patterns observed in `short-term` DOM dynamics to explain `long-term` SOM formation.

20 For instance, in their comprehensive review on organo-mineral interactions, Kleber et al.
21 (2015) question the view that strong bonds between organic matter and mineral surfaces
22 really guarantee slow turnover rates and hence long turnover times. Many factors that
23 potentially determine the long-term fate of sorbed organic matter are still not well understood.
24 They include exchange reactions between sorbed organic matter and new organic matter
25 inputs or the impact of mineral weathering activity of roots on stability of sorbed organic
26 matter. As proposed in Kaiser and Kalbitz (2012), the commonly observed increasing ¹⁴C age
27 of DOM with profile depth might be explained by temporal sorptive immobilization, followed
28 by microbial processing and re-release of altered compounds into soil solution. Keiluweit et
29 al. (2015) showed that root exudation of oxalic acid promotes the release of SOM sorbed onto
30 mineral surfaces into soil solution through dissolution of mineral phases. Taken together, the
31 view that DOM leached from litter decomposition sorbs onto mineral surfaces and then
32 contributes to stable SOM might be too simple. Processing of sorbed material may exert a

1 significant effect on SOM dynamics. This possibly prevents the long-term storage of plant-
2 derived aromatics in soil and explains the controversies outlined herein.

3 Besides oxalic acid, many other organic compounds are released from living roots (the so-
4 called `rhizodeposition`). Estimates suggest that rhizo-deposition constitutes a loss term of
5 17% (on average) of the net C assimilated by plants (Nguyen, 2003). It comprises low-
6 molecular weight compounds (organic acids, simple sugars, amino sugars, phenolics) as well
7 as high-molecular compounds (exoenzymes, root cells) (Wichern et al., 2008). Most of the
8 compounds are degraded quickly, but a smaller portion might contribute to stable SOM
9 (Nguyen, 2003; Pausch et al., 2013). The rhizosphere is considered a `hot-spot` in soil, where
10 microbial processes are accelerated as they are not C-limited (Kuzyakov and Blagodatskaya,
11 2015). Possibly, root activity not only fosters production, but also stabilization of microbial-
12 derived compounds in soil. To date, root activity effects on DOM dynamics and stabilization
13 of plant-derived aromatics at mineral surfaces are poorly studied. This is partly because
14 traditional analyses are focused on mixed soil samples, while the rhizosphere may only
15 comprise a small volume of bulk soil, and fluxes of DOM are averaged for a soil surface
16 (Kuzyakov and Blagodatskaya, 2015).

17 Recent investigation at the submicrometer scale using Nano Secondary Ion Mass
18 Spectrometry (NanoSIMS) or NEXAFS in combination with scanning transmission X-ray
19 microscopy suggest that SOM associated with clay-sized minerals exists in small patches of
20 varying chemical composition (Lehmann et al., 2008; Remusat et al., 2012; Vogel et al.,
21 2014). Distinct patches of predominantly aromatic C can be differentiated from patches
22 dominated by aliphatic C (Lehmann et al., 2008). Knowledge about processes controlling the
23 submicrometer-scale distribution of SOM on mineral surfaces is still limited. Some of the
24 patches are cell wall structures of microorganisms, which may contribute to stable SOM as
25 they are composed of insoluble polymers and possibly sorb to the mineral surface (Miltner et
26 al., 2012). Hence, stable sorbed organic matter might not only be derived from low-molecular
27 weight compounds. On the other hand, it needs to be considered that microbial-derived
28 compounds are continuously synthesized at the mineral surface. The microorganisms might
29 use some of the older C (^{14}C age) for synthesis of relatively labile compounds. The age of the
30 C atoms is, thus, decoupled from the stability of the organic matter, and microbial-derived
31 compounds may `mimic` a similar or even higher stability than the plant-derived compounds

1 (Gleixner, 2013). Hence, concentrations or ^{14}C age of microbial-derived compounds at
2 mineral surfaces do not per se allow for conclusions on their contribution to stable SOM.

3

4 **5 Implications and future research strategies**

5 The contradictions outlined herein limit our basic understanding on SOM formation, and our
6 ability to model and manage effects of global change on SOM stocks.

7 For instance, elevated atmospheric CO_2 levels can induce increasing concentrations of
8 aromatic components in plant litter (Cotrufo et al., 1994; Tuchman et al., 2002), and this
9 raises the question whether this causes enhanced or decreasing storage of SOM in mineral
10 soils. If aromatic matter is quickly degraded, and mineral-associated SOM primarily derives
11 from microbial sources (as suggested by the solid SOM line of evidence), a `microbial filter`
12 would control the built-up of stable SOM, which may then be determined by the microbial
13 substrate use efficiency (i.e., the amount of organic C used by the microbial community to
14 build biomass vs. the amount that is mineralized). As such, Cotrufo et al. (2013) hypothesized
15 that input of labile substrates fosters the build-up of stable SOM. Available data on effects of
16 litter quality and SOM formation are, however, inconsistent (Castellano et al., 2015), and we
17 believe that understanding on these effects is in part limited by uncertainties about the
18 incorporation of aromatics into stable SOM.

19 The issue is also related to the question of links between chemical structure of organic matter
20 and its persistence. It is oftentimes assumed that structural properties of plant-derived matter
21 do not determine stable SOM formation. This argument is based on data suggesting that
22 specific compound classes (lignin, cellulose, alkanes, proteins etc.) turn over faster than bulk
23 SOM (Schmidt et al., 2011). However, conclusions of DOM research imply that structure
24 plays a role for the behavior of organic compounds in soil, and eventually their contribution to
25 stable SOM: soluble aromatics may resist oxidation by microbes as they yield less energy
26 than other structures; furthermore, they bind to mineral surfaces due to carboxyl groups
27 attached to the rings.

28 How could we resolve the controversies? Based on our literature analysis we propose the
29 following research strategies:

- 30 • More studies addressing links between microbial processes, composition/fluxes of
31 DOM, and composition of solid-phase SOM are needed. The study by Kramer et al.

1 (2012) is a first attempt to relate the fluxes of aromatics to solid-phase SOM
2 properties. In particular, the presumed microbial processing of sorbed material,
3 causing desorption and subsequent mineralization or further transport in the soil
4 profile is poorly studied. Eventually, these processes might cause loss of aromatic
5 compounds. A related question is how root activity affects de-/sorption processes?

- 6 • Computer simulations could help to unravel the complex interrelationships between
7 DOM fluxes and solid-phase SOM composition. Recently developed models integrate
8 sorption, DOM transport, and microbial processes (Ahrens et al., 2015). In order to
9 address the problems discussed herein, effects of molecular structure on behavior of
10 the compounds in soil (e.g., differences in mineralization rate and affinity for sorption
11 between aromatics and non-aromatics) could be implemented in the models, in order
12 to develop novel hypotheses on turnover of plant-derived aromatics.
- 13 • Our knowledge is limited by the constraints in analysis of aromatics in soil.
14 Quantification of total amounts and source of aromatics in soil are still problematic.
15 Even if the problems cannot be fully solved with the currently available techniques,
16 there might be strategies to obtain improved estimates. The work of Hernes et al.
17 (2013) provides a first hint about how much lignin might be not accessible to CuO
18 oxidation analyses. The authors evaluated the extraction efficiency for lignin-derived
19 aromatics bound to different minerals. The size of the non-extractable fraction
20 depended strongly on the mineral. Almost all of the aromatics bound to ferrihydrite
21 were extractable, but for kaolinite the non-extractable fraction made >40%. But how
22 about extractability in soil under field conditions? Possibly, a combination of tracking
23 of C isotopes, DOM flux/ composition assessment, and analysis of solid-phase SOM
24 composition could provide better estimates on the hidden aromatics in soil.

Table 1. Evidence from field studies suggesting that dissolved aromatics (products of lignin depolymerization or tannins) disappear quickly once entering mineral soils.

Reference	Study site/ soil type	Result
Qualls and Haines 1991	Oak-hickory forest in mountain region of North Carolina; soil types: Umbric Dystrochrept, Typic Hapludult, Typic Dystrochrept	Selective removal of hydrophobic acids as DOM percolates through the mineral soil.
Cronan 1985	Forests, North-Western USA; soil types: Dystrochrept, Haplorthod	Selective removal of hydrophobic acids as DOM percolates through the mineral soil.
Zech et al. 1994	Spruce forest in Bavaria, Germany; Soil types: Typic Dystrochrepts, Entic Haplorthods, Typic Haplorthods	Selective removal of lignin-derived phenols (determined with the CuO method) as DOM percolates through the mineral soil.
Gallet and Pellissier 1997	Bilberry-spruce forest in Alps, France; soil type: Humoferric Podzol	Selective removal of lignin-derived phenols (as well as of total phenols) as DOM percolates through the mineral soil.
Kaiser et al. 2004	Spruce forest in Bavaria, Germany; Soil type: Haplic Arenosol	Selective removal of lignin-derived phenols, hydrophobic compounds, and total aromatic C as DOM percolates through the mineral soil.
Dai et al. 1996	Spruce forest, Maine; Soil type: Aquic Haplothods	Selective removal of hydrophobic acids and aromatics (¹³ C-NMR data) as DOM percolates through the mineral soil.
Lajtha et al. 2005	Coniferous forest, Oregon, USA; soil type: Typic Hapludands	Selective removal of hydrophobic acids as DOM percolates through the mineral soil.
Sanderman et al. 2008	Mediterranean climate; forest and grassland soils; soil types: Haplustols and Haplohumults	Decrease in UV absorbance (a measure for content of aromatics) as DOM percolates through the mineral soil.
Hassouna et al. 2010	Mediterranean climate; maize field; soil type: fluvic hypercalcaric cambisol	Decrease in contents of aromatic compounds (UV absorbance, fluorescence spectroscopy) in water-extractable organic matter with depth of the mineral soil.
Nakashini et al. 2012	Beech forest, Japan; soil: "brown forest soil"	Decrease in contents of hydrophobic acids in water-extractable organic matter with depth of the mineral soil.
