## 49 **Abstract**

50 Soil organic matter (SOM) is key to maintaining soil fertility, mitigating climate change,  
51 combatting land degradation, and conserving above- and below-ground biodiversity and  
52 associated soil processes and ecosystem services. In order to derive management options for  
53 maintaining these essential services provided by soils, policy makers depend on robust, predictive  
54 models identifying key drivers of SOM dynamics. Existing SOM models and suggested  
55 guidelines for future SOM modelling are defined mostly in terms of plant residue quality and  
56 input and microbial decomposition, overlooking the significant regulation provided by soil fauna.  
57 The fauna controls almost any aspect of organic matter turnover, foremost by regulating the  
58 activity and functional composition of soil microorganisms and their physical-chemical  
59 connectivity with soil organic matter. We show lots of quantitative examples that demonstrate a  
60 very strong impact of soil animals on carbon turnover, increasing or decreasing it by several  
61 dozen percent, sometimes even turning C sinks into C sources or vice versa. This is demonstrated  
62 not only for earthworms and other larger invertebrates but also for smaller fauna such as  
63 Collembola. We suggest that inclusion of soil animal activities (plant residue consumption and  
64 bioturbation altering the formation, depth, hydraulic properties and physical heterogeneity of  
65 soils) can fundamentally affect the predictive outcome of SOM models. Understanding direct and  
66 indirect impacts of soil fauna on nutrient availability, carbon sequestration, greenhouse gas  
67 emissions and plant growth is key to the understanding of SOM dynamics in the context of global  
68 carbon cycling models. We argue that explicit consideration of the soil fauna is essential to make  
69 realistic modelling predictions on SOM dynamics and to detect expected non-linear responses to  
70 global change, and we suggest that guidelines for future SOM modelling should implement the  
71 role of soil fauna. This had been the reason for bringing into being the COST (European  
72 Cooperation in Science and Technology) Action ES 1406 (KEYSOM – Soil fauna: key to new  
73 carbon models), which we briefly introduce. KEYSOM brings together biogeochemists and soil  
74 ecologists from 23 EU countries and provides a research network for improving SOM models by  
75 implementing the role of the soil fauna as a basis for sustainable soil management. An  
76 interdisciplinary platform of experimentalists and modellers is presently identifying the most  
77 burning research gaps and working on a new modelling approach. The current state of discussion  
78 is presented here. In the next years KEYSOM will also perform a large-scale field experiment,  
79 assure better access to experimental data, and inform decision makers.

## 85 **1. Introduction**

86 Despite continuous refinement over the past decades, estimates of the global carbon cycle still  
87 show large discrepancies between potential and observed carbon fluxes (Ballantyne et al., 2012;  
88 Schmitz et al., 2014). Soil organic matter (SOM) modelling is key to understand and predict  
89 changes in global carbon cycling and soil fertility in a changing environment. SOM models can  
90 facilitate a better understanding of the factors that underlie the regulation of carbon cycling and  
91 the persistence of SOM. The predictive power of current global SOM models is, however,  
92 limited, as the majority relies on a relatively restricted set of input parameters such as climate,  
93 land use, vegetation, pedological characteristics and microbial biomass (Davidson and Janssens,  
94 2006). In an overview on the performance of SOM models, none of 11 tested models could  
95 predict global soil carbon accurately, nor were 26 regional models able to assess gross primary

96 productivity across the US and Canada (Luo et al., 2015). Some years ago Schmidt et al. (2011)  
97 proposed eight “key insights” to enrich model predictions on the persistence of SOM. However,  
98 they ignored a major component of SOM dynamics, soil fauna, which play a fundamental role in  
99 most of the insights they propose (e.g. Fox et al., 2006; Jimenez et al., 2006; Osler and  
100 Sommerkorn, 2007; De Deyn et al., 2008; Wilkinson et al., 2009). By moving through and  
101 reworking soil, feeding on living plant roots, detritus and all types of microorganisms growing on  
102 these, soil animals are intimately involved in every step of SOM turnover. Omission of soil fauna  
103 from SOM models will, therefore, hamper the potential predictive power of these models.  
104 In a review focusing mostly on large mammals, terrestrial herbivores and aquatic ecosystems,  
105 Schmitz et al. (2014) recently called for “animating the carbon cycle”. Bardgett et al. (2013)  
106 argued that differential responses of various trophic groups of aboveground and belowground  
107 organisms to global change can result in a decoupling of plant-soil interactions, with potentially  
108 irreversible consequences for carbon cycling. Other research has shown that including soil animal  
109 activities could help clarifying the discrepancies in existing carbon models, based on a large-scale  
110 correlative field study (de Vries et al., 2013). Similar attempts to connect animal activity to  
111 carbon cycling occurred in the past (e.g. Lavelle and Martin, 1992; Lavelle et al., 1998; Lavelle  
112 and Spain, 2006; Osler and Sommerkorn, 2007; Brussaard et al., 2007; Sanders et al., 2014),  
113 without any further change in the structure of carbon models. This was partly due to a lack of  
114 communication between modellers and experimenters, but also because the magnitude of animal  
115 effects on SOM dynamics remains poorly quantified (Schmitz et al., 2014).  
116 Here we use the ‘key insights’ proposed by Schmidt et al. (2011) as a basis to review current  
117 evidence and to identify research needs on the relationship of soil fauna to SOM dynamics in  
118 order to justify the relevance of incorporating the soil fauna into SOM models. How important  
119 animal activities are for manifold geological and pedological processes has been reviewed  
120 repeatedly (e.g. Swift et al., 1979; Wilkinson et al., 2009). Due to their prime role in most  
121 processes in soil (Briones, 2014) we mostly focus on earthworms, but also give examples for  
122 other groups of soil fauna whose role in C turnover appears to be much more relevant than  
123 thought thus far (e.g. David, 2014). Recently, the significant impact of eight different species of  
124 ants over 25 years on mineral dissolution and accumulation of calcium carbonate has even been  
125 discussed in the context of geoengineering and carbon sequestration (Dorn, 2014). We point out  
126 regional differences in climate, soils and land use with respect to soil fauna composition,  
127 abundance and activity and derive implications for SOM modelling. Finally, we introduce a new  
128 COST Action (ES 1406) that is working on the implementation of soil fauna into SOM models,  
129 also exploring the pros and caveats in such a process.

130

## 131 **2. Key insights**

132 The eight ‘key insights’ compiled by Schmidt et al., 2011 are shown in Fig. 1, together with the  
133 most important activities of soil animals affecting them. As many animal-mediated processes are  
134 tightly interconnected, they also matter for most of these insights. For instance, aggregate  
135 formation in faeces simultaneously affects molecular structure, humic substances, physical  
136 heterogeneity and soil microorganisms. In the following text we briefly summarize the role of  
137 animal activities for each of the ‘key insights’. As a more detailed example of animal impacts on  
138 SOM turnover, we consider their role on soil aggregate formation in a separate section. Table 1  
139 contains quantitative examples of animal activity taken from different biomes and land use types,  
140 showing that earthworms alone strongly affect each of the ‘key insights’. However, much smaller  
141 soil animals can also have substantial effects on them (Table 1).

### 142 **2.1. Molecular structure**

143 Many soil animals ingest and process SOM (and accompanying microorganisms) in their gut  
144 system, where it is partly assimilated with the help of mutualistic gut microflora and partly

145 egested. Metabolisation alters the chemical structure of ingested SOM (Jiménez and Lal, 2006;  
146 Hedde et al., 2005; Coulis et al., 2009; Frouz, 2015b; Schmitz et al., 2014) and, consequently, the  
147 decomposition dynamics of animal faeces, which can be a substantial component of SOM  
148 (humification). Humification as such renders SOM less decomposable (Blume et al., 2009;  
149 Dickinson, 2012) whereas the alkaline milieu in invertebrate midguts accelerates mineralisation  
150 (e.g. Li and Brune, 2007).  
151 For instance, earthworm casts have species-specific NIR spectral signatures, indicating presence  
152 of specific organic compounds (Hedde et al., 2005). Under grass/legume pasture they are  
153 characterized by significant enrichment of slightly-altered plant residues in the sand particle size  
154 (> 53 µm). CPMAS <sup>13</sup>C NMR (Cross-Polarization Magic Angle Spinning Carbon-13 Nuclear  
155 Magnetic Resonance) spectra showed that earthworm casts and surrounding soil were dominated  
156 by carbohydrates, with a decrease of O-alkyl C and an increase of alkyl C with decreasing  
157 particle size (Guggenberger et al., 1996). Moreover, earthworms likely possess a unique  
158 capability of neutralizing plant polyphenols that otherwise strongly decrease decomposition rates  
159 of fresh plant litter (Liebeke et al., 2015). Micro- and mesofauna excrete ammonium or dissolved  
160 organic carbon (Filser, 2002; Fox et al., 2006; Osler and Sommerkorn, 2007), and affect the  
161 quantity of microbial metabolites (Bonkowski et al., 2009). Gut passage, defecation, excretion  
162 together with bioturbation by macro- and mesofauna facilitate humification and decomposition,  
163 altering also nutrient stoichiometry (Bohlen et al., 2004). These modifications in the molecular  
164 structure of SOM due to soil fauna activity have significant effects on its dynamics (Swift et al,  
165 1979; Guggenberger et al., 1995; Blume et al., 2009; Dickinson, 2012 and other references  
166 related to points 1 and 2 in Table 1).

## 167 **2.2. Humic substances**

168 The term “humic substances” may be considered problematic by part of the scientific community:  
169 neither is the concept itself clear, nor is there any evidence that the often mentioned highly  
170 complex large organic molecules play any relevant role in organic matter stabilisation under  
171 natural conditions (Schmidt et al., 2011; Lehmann and Kleber, 2015). However, here we stick to  
172 it when referring to the “insights”, simply for reasons of consistency with the article our  
173 argumentation is based on Schmidt et al. (2011). We acknowledge that “humus” or “humic  
174 substances” represent a continuum of more or less decomposed dead organic matter of which  
175 energy content and molecule size mostly should decrease over time, and that water solubility,  
176 sorption to the mineral matrix and accessibility for microorganisms are highly relevant for OM  
177 turnover (Lehmann and Kleber, 2015).

178 Humic substances are formed during the gut passage: organic matter in young soils and humic  
179 horizons almost completely consists of soil animal faeces (Lavelle, 1988; Martin and Marinissen,  
180 1993; Brussaard and Juma, 1996). Humus forms mainly comprise animal casts, e.g. casts of ants,  
181 isopods, millipedes, beetle larvae or termites in deadwood, of insect larvae and spiders in leaf  
182 litter, or casts of collembolans, mites and enchytraeids in raw humus. In his review, David (2014)  
183 considered macroarthropod casts being a factor of partial SOM stabilisation, rather than hotspots  
184 of microbial activity. The dark colour of casts (compared to the ingested organic material)  
185 visually demonstrates the strong chemical OM modification in animal guts, which is  
186 accompanied by a substantial physical modification. Clay-humus complexes, physically  
187 protecting organic matter (Jiménez and Lal, 2006), are mainly faeces of earthworms and  
188 diplopods (see also Sect. 2.5 on physical heterogeneity). Due to differences in feeding  
189 preferences, gut microflora, SOM quantities consumed etc. of soil animals, their faeces vary in  
190 size, shape and quality not only between fauna groups, but also between species within one group  
191 (see Sect. 3 on aggregate formation). Discovering the important role of animal faeces in  
192 humification is essential to improve our understanding of carbon dynamics in soil.

193  
194

### 195 **2.3. Fire-derived carbon**

196 Microbial recolonisation of burned sites is mediated by wind and soil animals that survived in  
197 soil or emigrated from neighbouring areas, e.g. by macro- and mesofauna, birds and mice  
198 (Malmström, 2012; Zaitsev et al., 2014). Besides, soil fauna also ingest the charcoal particles  
199 (Eckmeier et al., 2007; see Table 1). Due to animal activity, charcoal is sorted by size and  
200 translocated down the soil profile. Mice and earthworms (Eckmeier et al., 2007) and the tropical  
201 earthworm *Pontoscolex corethurus* (Topoliantz and Ponge 2003; Topoliantz et al., 2006) had  
202 been suggested as responsible for rapid incorporation of charcoal into the soil. Quantitative data  
203 are however scarce (Table 1). In spite of potentially great importance, the effect of soil animals  
204 on the fate of the “black carbon” in soil remains practically unknown (Ameloot et al., 2013).

### 205 **2.4. Roots**

206 Plant roots preferably grow in existing soil cavities (Jiménez and Lal, 2006), mostly formed by  
207 soil fauna (Wilkinson et al, 2009). Both burrowing and non-burrowing soil animals have a strong  
208 impact on root growth, allocation, length and density (Brown et al., 1994; Bonkowski et al.,  
209 2009; Arnone and Zaller, 2014). Animal grazing of root bacteria and mycorrhiza affects their  
210 activity and community composition, and animal excreta are enriched in micronutrients and  
211 selectively affect plant nutrition (Brown, 1995; Filser, 2002; Brussaard et al., 2007). Root  
212 herbivores and rhizosphere grazers affect C allocation of roots (Wardle et al., 2004) and largely  
213 regulate nutrient acquisition and plant productivity (Bonkowski et al., 2009). Not only root  
214 herbivores, but also saprotrophic/microbivorous soil animals may obtain a significant proportion  
215 of energy from plant roots (Pollierer et al., 2007). This suggests an animal-mediated regulatory  
216 loop that connects plant roots and SOM.

### 217 **2.5. Physical heterogeneity**

218 Animals fragment any organic residues, perform bioturbation, distribute organic matter and  
219 generate smaller and larger organic matter hot spots (e.g. faecal pellets, ant and termite mounds).  
220 According to body size, they act at various spatial scales, from micro-aggregates to landscapes  
221 (Ettema & Wardle, 2002; Jouquet et al., 2006). Mounds and burrows made by soil fauna are  
222 obvious signs of physical heterogeneity created by ecosystem engineers (Meysmann et al., 2006;  
223 Wilkinson et al., 2009; Sanders et al., 2014), which significantly affect microorganisms, plants  
224 (Chauvel et al., 1999; Frelich et al., 2006), aggregate stability (Bossuyt et al., 2005; 2006),  
225 hydraulic properties (Bottinelli et al., 2015; Andriuzzi et al., 2016), sorption and degradation of  
226 sparingly soluble organic compounds (Edwards et al., 1992; Bolduan and Zehe, 2006) and C  
227 emissions (Wu et al., 2013; Lopes de Gerenyu et al, 2015). Earthworms in particular feed on  
228 organic and mineral parts of the soil and mix them (Eckmeier et al., 2007; Wilkinson et al.,  
229 2009). The resulting clay-organic matter complexes considerably increase SOM retention of soils  
230 (Jiménez and Lal, 2006; Fox et al., 2006; Brussaard et al., 2007), although C loss from fresh casts  
231 is much higher than from surrounding soil (Zangerlé et al., 2014). The impact on soil processes  
232 and physical heterogeneity varies considerably between different groups of ecosystem engineers  
233 (Jouquet et al., 2006; Bottinelli et al., 2015). For instance, some earthworm species strongly  
234 affect their physical environment while others are more linked to the soil organic matter content  
235 (Jiménez et al. 2012).

### 236 **2.6. Soil depth**

237 In most soil types, pore volume, carbon content, associated biotic processes and temperature  
238 variability strongly decrease with depth whereas other parameters such as bulk density and water  
239 content increase – all of which significantly affect SOM turnover rates. The depth of organic  
240 horizons varies with soil type, from almost zero to several metres. Thus, Schmidt et al. (2011)

241 identified soil depth as another “key insight”. Yet, digging animals play a key role in the  
242 development of soil depth. A considerable part of physical heterogeneity are animal burrows that  
243 can reach several meters deep. Bioturbation (e.g. by earthworms, termites, ants, beetle and  
244 Diptera larvae, spiders, solitary bees and wasps, snails, isopods and amphipods, puffins, lizards,  
245 porcupines, pigs, moles, voles, rabbits, foxes, or badgers) is a key process to the formation of soil  
246 depth, soil structure and associated C translocation, as shown by several examples in Table 1 and  
247 reviewed e.g. by Wilkinson et al. (2009).

## 248 **2.7. Permafrost**

249 Due to unfavourable environmental conditions (resulting in low animal biomass, activity and  
250 diversity), there is only little impact of fauna in permafrost soils (De Deyn et al., 2008). However,  
251 fauna invasions, especially of above-mentioned soil engineers, due to soil melting in tundra and  
252 boreal forests are likely to have drastic effects (Frelich et al., 2006; Van Geffen et al., 2011). Data  
253 on earthworm invasions in North American forests (Bohlen et al., 2004; Frelich et al., 2006;  
254 Eisenhauer et al., 2007) show that they must be taken into consideration in carbon-rich soils,  
255 particularly in melting permafrost soils (Frelich et al., 2006; Schmidt et al., 2011) where they  
256 may affect many soil functions.  
257

## 258 **2.8. Soil microorganisms**

259 Soil fauna comprise ecosystem engineers as well as an armada of mobile actors connecting  
260 elements of the soil system, mediating microbial processes (Briones, 2014). Countless isopods,  
261 ants, termites, enchytraeids, microarthropods, nematodes or protozoans make large contributions  
262 to SOM turnover underground (Persson, 1989; Filser, 2002; Wardle et al., 2004; Fox et al., 2006;  
263 Osler and Sommerkorn, 2007; Wilkinson et al., 2009; Wu et al., 2013). They affect the activity  
264 and community composition of soil microorganisms in multiple ways such as feeding, burrowing,  
265 facilitating the coexistence of different fungal species (Crowther et al., 2011) or by modifying  
266 micro-habitat conditions. Litter comminution by detritivores increases SOM accessibility for  
267 microorganisms, and propagules are dispersed with body surface and casts. The gut environment  
268 provides protected microsites with modified biotic and abiotic conditions, which increase  
269 bacterial abundance substantially – e.g. by three orders of magnitude in earthworm guts (Edwards  
270 and Fletcher, 1988). Grazing affects microbial biomass, activity and community composition, and  
271 animal excreta modify nutrient availability for microorganisms (Brown, 1995; Filser, 2002).  
272

## 273 **3. Aggregate formation**

274 The modern view on the stability of organic matter in soils requires a thorough understanding of  
275 aggregate structure and formation including the role of soil biota (Lehmann and Kleber, 2015).  
276 Soil aggregation is the process by which aggregates of different sizes are joined and held together  
277 by different organic and inorganic materials. Thus, it includes the processes of formation and  
278 stabilization that occur more or less continuously, and can act at the same time. With clay  
279 flocculation being a pre-requisite for soil aggregation, the formation of aggregates mainly occurs  
280 as a result of physical forces, while their stabilization results from a number of factors, depending  
281 in particular on the quantity and quality of inorganic and organic stabilizing agents (Amézketa,  
282 1999).

283 By bioturbation, feeding and dispersal of microbial propagules soil animals regulate all of the  
284 above forces and agents, and are therefore a crucial factor in the formation and stabilisation of  
285 soil aggregates. Earthworms, many insect larvae and other larger fauna may stabilize aggregate  
286 structure by ingesting soil and mixing it intimately with humified organic materials in their guts,  
287 and egesting it as casts or pellets (Tisdall and Oades, 1982; Oades, 1993).

288 Earthworms have a direct and fast impact on microaggregate formation and the stabilization of  
289 new C within these microaggregates (Bossuyt et al., 2005) (Table 1). There are several  
290 mechanisms to explain the increase of micro- and macroaggregate stability by earthworms, but no  
291 mechanism has been quantified in relation to population size yet. Effects are related to ecological  
292 groups of earthworms, associated with feeding habit, microhabitat in the soil profile, and burrow  
293 morphology. However, irrespective of this classification, species may enhance or mitigate soil  
294 compaction (Blanchart et al., 1997; Guéi et al., 2012). The tensile strength of casts appears to be  
295 species dependent: for example, the casts of *Dendrobaena octaedra* have a lower tensile strength  
296 compared to those of *L. terrestris* (Flegel et al., 1998). Similarly, organic carbon and water-stable  
297 aggregation was significantly higher in casts of *L. terrestris* than in casts of *A. caliginosa*  
298 (Schrader and Zhang, 1997).

299 Some research, however, suggests that earthworm activity can also evoke soil degradation.  
300 Shipitalo and Protz (1988) proposed that ingestion of soil by earthworms results in disruption of  
301 some existing bonds within micro-aggregates and realignment of clay domains. Therefore, fresh  
302 casts are more dispersible than uningested soil, contributing to soil erosion and crusting.  
303 Significant improvement in the water stability of fresh, moist casts only occurs when  
304 incorporated organic debris from the food sources is present and when moist casts are aged or  
305 dried. Nevertheless, in the long term, casting activity enhances soil aggregate stability.

306 However, our understanding of the contribution of soil fauna to aggregate formation and  
307 stabilization is limited, and mostly qualitative in nature. Different methodologies complicate the  
308 comparison among aggregate stability data (Amézketa, 1999). Data in terms of functional  
309 response to density are limited as many studies have been conducted in arable systems, where the  
310 diversity and abundance of soil animals are reduced as a consequence of tillage, mineral  
311 fertilizers and pesticide use. Recently, some studies have emerged. A negative correlation  
312 between earthworm abundance and total macroaggregates and microaggregates within  
313 macroaggregates in arable treatments without organic amendments could be linked to the  
314 presence of high numbers of *Nematogonia lacuum*, an endogeic species that feeds on excrements  
315 of other larger epigeic worms and produces small excrements (Ayuke et al., 2011). Under the  
316 conditions studied, differences in earthworm abundance, biomass and diversity were more  
317 important drivers of management-induced changes in aggregate stability and soil C and N pools  
318 than differences in termite populations. Another study highlighted that in fields converted to no-  
319 tillage earthworms incorporated C recently fixed by plants and moved C from soil fragments and  
320 plant residues to soil aggregates of >1 mm (Arai et al., 2013). Thus, soil management practices  
321 altering fauna activities may have a significant effect on the re-distribution of soil organic matter  
322 in water-stable aggregates, impacting agronomically favourable size fractions of water-stable  
323 macro-aggregates, and water-stable micro-aggregates which are the most important source of  
324 carbon sequestration (Šimanský and Kováčik, 2014).

325

#### 326 **4. Regional differences in climate, soils and land use**

327 In a global meta-analysis spanning several continents, García-Palacios et al. (2013) show that  
328 across biomes and scales the presence of soil fauna contributes on average 27% to litter  
329 decomposition. Depending on the situation this contribution can be substantially lower or higher.  
330 For instance, the authors report an average increase in decomposition rates of 47% in humid  
331 grasslands whereas in coniferous forests this figure amounts to only 13%. The high impact of soil  
332 fauna in humid grasslands is all the more important as such grasslands are among those  
333 ecosystems that are most severely affected by global environmental change.

334 Many of our examples refer to earthworms and temperate regions as they have been studied most  
335 intensively. However, we suggest that any dominant group of soil fauna, irrespective of body size  
336 or the ability to create larger soil structures, may substantially affect carbon dynamics. Table 1  
337 gives a number of respective case studies. The key players and specific effects of soil animals  
338 vary across space (Fig. 2), with increasing importance for SOM dynamics in humid-warm and

339 nutrient-limited conditions (Persson, 1989; Filser, 2002; Wardle et al., 2004; Fox et al., 2006;  
340 Osler and Sommerkorn, 2007; De Deyn et al., 2008; Briones, 2014). Once key players in a given  
341 ecosystem have been identified, more detailed information on their biology is required, in  
342 particular on their activity, their ecological niche and corresponding tolerance limits. All this  
343 varies with species, and often extremely within one systematic group. Variation in drought or soil  
344 temperature towards limiting conditions will first increase (stress response, e.g. downward  
345 migration) and then strongly decrease activity (mortality or transition to inactive resting stage).  
346 Some key players will exhibit high abundance and be extremely active throughout the year  
347 (Wilkinson et al., 2009), others might only be moderately relevant during a short period of time;  
348 the contribution of a third group might be considered insignificant.  
349 Also ecosystem engineers differ between soil types, biomes and land-use types, from rodents and  
350 ants in dry areas to termites, earthworms and millipedes in tropical rainforests. They consume  
351 different types of organic matter, make deep or shallow, narrow or wide burrows, and differ in  
352 aggregation behaviour (e.g. more or less regularly distributed earthworms versus distinct ant nests  
353 and termite mounds). Accordingly, their role in SOM re-distribution and turnover differs as well.  
354 In cold ecosystems – where, together with wetlands and peatlands, the majority of terrestrial  
355 carbon is stored (Davidson and Janssens, 2006) – the response of detritivores to climatic change  
356 is expected to be most pronounced (Blankinship et al., 2011). Melting of permafrost soil might  
357 lead to northward expansion of soil macro-invertebrates, associated with accelerated  
358 decomposition rates (van Geffen et al., 2011). Further examples are shown in Table 1.  
359 More information is needed on how existing abiotic and biotic constraints to SOM decomposition  
360 will vary with changing climate and in different regions (Davidson and Janssens, 2006). Finally,  
361 human activity comes into play: any significant land use change, particularly soil sealing and  
362 conversion of native forest to agricultural land, has dramatic consequences for abundances and  
363 species composition of soil communities. The same holds true for management intensity and  
364 pollution (Filser et al., 1995; Filser et al., 2002; Filser et al., 2008; De Vries et al., 2012). Yet,  
365 even seemingly harmless activities can be significant, as we will show for the case of fishing in  
366 the end of Sect. 5 – pointing out the relevance of human activities for soil fauna beyond impact  
367 on global warming and land use change. How we address all this biogeographical and ecological  
368 variation is shown in Sect. 5 and 6.

## 369 **5. Implications for modelling**

370 As there is no unambiguous scientific support for the widespread belief in “humic substances”  
371 (here defined as very large and highly complex, poorly degradable organic molecules with  
372 manifold aromatic rings; Lehmann and Kleber, 2015), the question how long organic carbon  
373 remains in soil is largely related to a) physical protection and b) how often the once  
374 photosynthesized dead organic matter is recycled in the soil food web. For both processes soil  
375 animals are of great importance, as we have shown above. Biomass and abundance of soil  
376 animals are generally constrained by temperature, humidity and food (living or dead organic  
377 matter). However, the effects of these constraints on their activity are not simply additive, nor is  
378 there any simple relation between biomass and activity. For example, despite overall  
379 unfavourable conditions for the majority of soil organisms, burrowing activity in deserts can be  
380 extremely high (Filser and Prasse, 2008). Moreover there is increasing evidence that fauna effects  
381 on energy and nutrient flow can be at least partly decoupled from other abiotic and biotic factors  
382 (Frouz et al., 2013). De Vries et al. (2013) even concluded that “Soil food web properties strongly  
383 and consistently predicted processes of C and N cycling across land use systems and geographic  
384 locations, and they were a better predictor of these processes than land use”. This implies that  
385 knowledge of fauna may increase our prediction power. The thermodynamic viewpoint makes the  
386 issue even more relevant: reaction speed increases with temperature, but most soil organisms are  
387 rather adapted to relatively cool conditions and might thus be pushed beyond their niche limits –  
388 with eventually negative consequences on their activity, see Sect. 4.

389 Changes in climate (Blankinship et al., 2011), land use (Filser et al. 2002; Tsiafouli et al., 2014),  
390 resource availability and biotic interactions (De Vries et al., 2012; see Table 2) alter the  
391 distribution, community composition, activity and associated impact of soil animals on  
392 distribution and turnover rate of SOM (Wall et al., 2008) to the extent that underlying  
393 assumptions of SOM models may no longer be valid (Swift et al., 1998; Bardgett et al., 2013;  
394 Schmitz et al., 2014). Therefore it is opportune to include approaches that have been developed  
395 during the past decades (Filser, 2002; Jiménez and Lal, 2006; Osler and Sommerkorn, 2007;  
396 Brussaard et al., 2007; Meysmann et al., 2006; Wall et al., 2008; Sanders et al., 2014). For  
397 instance, implementing earthworm activity in the CENTURY model (Lavelle et al., 2004)  
398 revealed a 10% loss of the slow C pool without earthworms within 35 years. For this purpose,  
399 observations on long-term incubated earthworm casts and sieved control had been used as a  
400 reference. Afterwards earthworm activity was simulated with CENTURY by replacing the active  
401 and slow soil C decomposition rates of the model with those obtained by calibration with the  
402 control soil.

403 Without considering the role of animals, models are less accurate: in a field study spanning four  
404 countries from Sweden to Greece, soil food web properties were equally important as abiotic  
405 factors and predicted C and N cycling processes better than patterns of land use (De Vries et al.,  
406 2013). In their study, earthworms enhanced CO<sub>2</sub> production whereas Collembola and  
407 bacterivorous nematodes increased leaching of dissolved organic carbon. Mechanistic  
408 experiments confirm that earthworms have a detrimental effect on the greenhouse gas balance  
409 under nitrogen-rich conditions (Lubbers et al., 2013) and under no-till (Lubbers et al., 2015).  
410 Inclusion of group-specific diversity of mesofauna in models of global-scale decomposition rates  
411 increased explained variance from 70 to 77% over abiotic factors alone (Wall et al., 2008). Also  
412 García-Palacios et al (2013) provide additional evidence on the argument that soil fauna activity  
413 is not merely a product of climate, soil properties and land use but an independent parameter.  
414 These examples indicate that the actors that play an important role in SOM dynamics should be  
415 considered in SOM models.

416 Model parameters are often measured *in situ* at relatively large spatial scales – at least compared  
417 with the size or activity range of most soil animals. As a result, the fauna effect is *de facto*  
418 included, although not appreciated (Swift et al., 1998). However, in many cases parameters are  
419 measured or extrapolated by combining *in situ* methods (e.g. monitoring of gas flux or litterbag  
420 experiments) and *ex situ* techniques such as laboratory experiments at controlled, highly  
421 simplified conditions. Especially the results of the latter may be sensitive to neglecting soil fauna.  
422 A relationship between animal activity and C turnover may vary with scale, for instance when  
423 soil properties or animal abundance differ at larger distance. However, as data is often  
424 insufficient, it will be context-dependent if the inclusion of fauna is sensible or not (see Sect. 6).  
425 On the other hand, not taking explicitly into account the spatial heterogeneity created by soil  
426 fauna in field measurements might lead to substantial errors in calculating carbon budgets (Wu et  
427 al., 2013; Lopes de Gerenyu et al, 2015). It is thus crucial to develop sound (and biome-specific)  
428 strategies for combining *in-* and *ex-situ* measurements as parameters in more realistic SOM  
429 models.

430 Next to space, scale effects also apply to temporal patterns – which poses a great challenge for  
431 SOM modelling as most studies refer to rather short periods of time. We illustrate this by the  
432 comparatively well studied impact of invasive earthworms. The meta-analysis of Lubbers et al.  
433 (2013) suggests that the effect of earthworms on total SOC contents is on average relatively  
434 small. In contrast, in certain situations earthworms can strongly affect greenhouse gas emission.  
435 These data were however mainly obtained in relatively short-term experiments. Over a period of  
436 months to years and even decades, earthworms can reduce C decomposition by physical  
437 protection of C in ageing casts (Six et al., 2004, see Table 1).

438 Thus, long-lasting effects of invasive earthworms on the total SOC storage cannot be determined  
439 with certainty in short-term experiments, whereas field observations are rather controversial. For  
440 instance, Wironen and Moore (2006) reported ca. 30% increase in the total soil C storage in the  
441 earthworms-invaded sites of an old-growth beech-maple forest in Quebec. Other studies (e.g.

442 (Sackett et al., 2013; Resner et al., 2014) suggest a decrease in C storage. Zhang et al (2013)  
443 introduced the sequestration quotient concept to predict the overall effect of earthworms on the C  
444 balance in soils of different richness, but the question remains strongly understudied.  
445 These well documented examples of the impact of earthworms on soil C storage are related to  
446 invasive species. The presence of these species cannot be inferred directly from the climatic, soil  
447 and vegetation properties. The distributions of European invasive earthworms in North America,  
448 North European forests or South Africa are largely driven by human activity. Often fishing (due  
449 to lost baits), imported plants or potting material of colonizing farmers (Reinecke, 1983) are more  
450 important for these than habitat transformation – without human’s help earthworms are not active  
451 invaders (Stoscheck et al., 2012; Tiunov et al., 2006; Wironen and Moore, 2006). Thus the  
452 presence of earthworms can be an environment-independent parameter of SOM dynamics.  
453 Another fundamental issue in the large-scale approach is often neglected: When including the  
454 effects of the soil fauna implicitly, this assumes that the soil fauna will always have the same  
455 effects under the same conditions, and hence that the soil fauna is essentially static. This  
456 assumption is increasingly unrealistic in a fast-changing world where both biodiversity and the  
457 climate are changing at accelerated paces, and where we are likely to witness major  
458 reorganisations of plant, animal and microbial communities. Therefore explicit representation of  
459 the soil fauna, where possible, should increase the predictive ability of soil models.  
460 Given the fact that this issue had been raised decades back (see above) it appears somewhat  
461 astonishing that attempts to pursue it have not yet made any significant progress. We believe  
462 there are mainly three reasons for this: a) missing information, b) too much detail, irrespective of  
463 spatial scale, and c) too little communication between empiricists and modellers. This is why we  
464 decided to bring into life a COST Action as an appropriate instrument to bridge these gaps. The  
465 next section gives an overview on it.

## 466 **6. Ways to proceed: COST Action ES 1406**

467 Based on the arguments compiled here, a COST Action entitled “Soil fauna - Key to Soil Organic  
468 Matter Dynamics and Modelling (KEYSOM)” was launched in March 2015  
469 ([http://www.cost.eu/COST\\_Actions/essem/ES1406](http://www.cost.eu/COST_Actions/essem/ES1406)). An interdisciplinary consortium of soil  
470 biologists and biogeochemists, experimenters and modellers from 23 European countries plus the  
471 Russian Federation and the USA cooperates to implement soil fauna in improved SOM models as  
472 a basis for sustainable soil management. Main aim of KEYSOM is to test the hypothesis that the  
473 inclusion of soil fauna activities into SOM models will result in a better mechanistic  
474 understanding of SOM turnover and in more precise process descriptions and output predictions  
475 of soil processes, at least locally. A number of workshops address key challenges in  
476 experimentation and modelling of SOM and soil fauna and support research exchange and access  
477 to experimental data. Special attention is given to education of young scientists. The Action  
478 comprises four Working Groups (WG) with the following topics:

- 479 1. Knowledge gap analysis of SOM – soil fauna interactions;
- 480 2. Potentials and limitations for inclusion of soil fauna effects in SOM modelling;
- 481 3. Data assemblage and data sharing;
- 482 4. Knowledge management and advocacy training.

483 After an intensive and enthusiastic workshop held in Osijek, Croatia in October 2015, first  
484 activities included compilation of literature, the setup and permanent update of a website  
485 (<http://keysom.eu/>). Meanwhile short-term scientific missions for early-career scientists have  
486 been launched (<http://keysom.eu/stsm/KEYSOM-STSMs-are-open-for-application>), aiming for  
487 complementing the Action’s activities. The second workshop was held in Prague in April 2016.

488 Next to a first compilation of knowledge gaps in this article, present activities of KEYSOM  
489 involve

- 490 - a literature review on biome-specific effects of soil fauna impact on SOM turnover
- 491 - a literature review on the impact of soil fauna other than earthworms on SOM turnover
- 492 - a compilation of the potentials and limitations of existing SOM models
- 493 - the development of a simple SOM model based on the current state of knowledge
- 494 exchange between empiricists and modellers within KEYSOM
- 495 - the preparation of a common European-wide field study into the impact of soil fauna
- 496 composition and abundance on SOM breakdown, distribution and aggregate formation,
- 497 which will start in autumn 2016
- 498 - the preparation of a summer school, to be held in early October 2016 in Coimbra,
- 499 Portugal

500 Fig. 3 illustrates the present state of our interdisciplinary discussions, providing a roadmap how  
501 SOM models could be supplemented with the effects of soil fauna. In the first phase, empiricists  
502 (Fig. 3A) and modellers (Fig. 3B) work in parallel. Mutual exchange between these groups is  
503 guaranteed by the regular workshop meetings such as in Osijek and Prague.

504 The stepwise approach functions like a decision tree, with various feedback loops and options at  
505 every step if and how known effects of soil fauna could be implemented into SOM. It also  
506 identifies under which circumstances additional research (literature review or experimental  
507 studies) needs to be initiated before proceeding further. As many existing models, also the new  
508 model should have a modular structure so that different modules can be used and combined  
509 according to the respective biome- and scale-specific scenario (Fig. 3C). It can also be seen that  
510 we do not aim to include every detail everywhere: in some situations (Fig. 3A) the impact of soil  
511 fauna on SOM dynamics might be too small (or existing information too scanty) to be included,  
512 and not all input parameters will be feasible or relevant at each scale (miniature in Fig. 3C). This  
513 keeps the model manageable, and also flexible enough to allow for more precise predictions in  
514 critical scenarios, like in the case of earthworm invasions sketched in Sect. 5. We generally think  
515 that focusing on such critical scenarios (analogous to e.g. global biodiversity hotspots) is a crucial  
516 precondition for well-informed management decisions, one of the final aims of KEYSOM.

517 As an example, box no. 1 in Fig. 3A stands for the first literature review in the above list.  
518 Depending on the outcome, for each biome a decision will be made if the impact of fauna on  
519 SOM turnover is unknown, relevant or low. In the first case, more research is needed, in the last  
520 case the faunal effect can be ignored. Depending on the outcome of additional research, the  
521 knowledge base will be improved and the decision between ignoring and proceeding further can  
522 be made anew. If a strong effect is expected, the next question (box no. 2 in Fig. 3A) will be  
523 addressed and so forth.

524 Once the procedure in Fig. 3A has reached box no. 4, intensive exchange with modellers (Fig.  
525 3B) is mandatory to identify the relevant model parameters and the type of functional relationship  
526 (box 5). Mechanistic aspects (such as chemical transformation in the gut, physical protection  
527 within aggregates or impact on hydraulic soil properties via digging) are of prime importance  
528 here as each of these examples may have different effects on C turnover. Effects of fauna  
529 abundance or biomass (in comparison to presence-absence) on the shape of the function will be  
530 addressed as well. Note, however, that to date necessary data for such an approach appear to be  
531 limited (García-Palacios et al., 2013). – In the meantime, the modellers will have developed a  
532 basic model structure and compare it with the structures of existing SOM models concerning  
533 potentials and limitations for including fauna effects (Fig. 3B).

534 The second phase (Fig. 3C) starts with the practical tests of the collected model parameters  
535 (boxes 6 and 7), using data that have been compiled by then by WG 3, allowing for selecting the  
536 best model (box 8). At this point, spatial scale comes into play, which is likely to be the most  
537 critical issue: As we have seen also while preparing this article, existing data on the impact of soil

538 fauna on SOM turnover are highly diverse, from short-term and often highly artificial  
539 experiments at controlled conditions to large-scale correlative field studies in all kinds of  
540 different environments (and with a strong bias what comes to certain biomes). The type of  
541 relationship between faunal abundance and SOM turnover will in most cases vary with scale. If  
542 data for different scales is not available (box 9), further research is needed. In the second case,  
543 one can proceed with boxes 10 and 11.

544 Importantly, the idea is not to include the fauna in every situation everywhere. Rather we aim at  
545 identifying critical hotspots and scenarios (see above) where faunal activities play a crucial role  
546 in SOM turnover, as demonstrated in Sect. 5. Due to the abovementioned differences between  
547 biomes and scale effects, these scenarios will be biome- and scale-specific. An example is shown  
548 in the lower left corner of Fig. 3C. For Biome A, hydraulic properties have been identified to be  
549 crucial for SOM dynamics. Thus, data is needed on animals that affect these, such as digging  
550 earthworms or rodents. Instead, the analyses for Biome B have revealed aggregate structure and  
551 microorganisms being most relevant – claiming for respective data at the small scale. On a larger  
552 scale (shaded miniature in Fig. 3C), such data for microorganisms might not be available, which  
553 implies proceeding with aggregate structure alone.

554 Overall, the whole approach requires a modular model structure, allowing for using different  
555 models according to the respective situation and data availability. This is what WG 2 is currently  
556 developing. – Certainly all the research outlined here cannot be done within one single COST  
557 Action. Based on the outcome of our work, we hope to come up with a more detailed roadmap  
558 how to further proceed to improve SOM modelling. This roadmap, together with what could be  
559 achieved with the limited resources of KEYSOM, will provide information material, decision  
560 tools and management options for decision makers and politicians (WG 4).  
561

## 562 **7. Conclusions and outlook**

563 Understanding and modelling SOM is essential for managing the greenhouse gas balance of the  
564 soil, for land restoration from desertification, for sustaining food production and for the  
565 conservation of above- and belowground biodiversity and associated ecosystem services (Nielsen  
566 et al., 2015). Soil animal abundance, biodiversity, species traits and interactions are crucial for  
567 SOM turnover (Chauvel et al., 1999; Bohlen et al., 2004; Wardle et al., 2004; Wall et al., 2008;  
568 Uvarov, 2009). In Table 2 we give recommendations how the known impact of soil fauna on  
569 SOM turnover could be used for improving carbon models. Due to the pronounced differences  
570 with respect to climate, soil and land use outlined above, it is important that these  
571 recommendations are considered region- and scale-specific, taking into account the key players  
572 and their specific activities in the respective area.

573

## 574 **Author contribution**

575 J. Filser wrote the article, prepared Fig. 1 and 3 and the tables and compiled the contributions  
576 from all co-authors. These are listed according to their quantitative and qualitative impact on the  
577 manuscript, except for J.J. Jiménez who was placed last as he is the chair of COST Action ES  
578 1406 (KEYSOM). L. Brussaard suggested including Fig. 2.

579

580

## 581 **Acknowledgements**

582 Three anonymous referees are acknowledged for their critical comments which significantly  
583 contributed to the revision of the original manuscript. We thank Antje Mathews for compiling the  
584 references and editing the manuscript. Oxford University Press and Wiley and Sons are  
585 acknowledged for the permission to include Fig. 2. This paper is a contribution to the COST  
586 Action ES1406 (KEYSOM) lead by the first and last author. A lot of the writing was inspired by  
587 the lively discussions within the workshop meetings of KEYSOM – thanks to all contributors!  
588 We thank COST Association for financially supporting collaboration and networking activities  
589 across Europe.

841 **Tables**

842 **Table 1.** Quantitative examples of the impact of earthworms and selected groups of other soil fauna on  
 843 soil properties and processes involved in soil organic matter (SOM) turnover. If not mentioned otherwise,  
 844 any numbers or percentages refer to the control without fauna. Selected particularly striking examples are  
 845 printed in bold.

Insight*	Examples	Source
	<b>Earthworms</b>	
1. Molecular structure	An indicator of lignin degradation in earthworm casts was twice that of the surrounding soil	Guggenberger et al., 1995
2. Humic substances	Introduced earthworms can double microaggregate formation and the stabilization of new C in the topsoil	Marashi and Scullion, 2003; Six et al., 2004
	C protection is promoted by microaggregates within large macroaggregates, and earthworms can add 22% anew to this C pool	Bossuyt et al., 2005
	Exclusion of earthworms reduced SOC accumulation by 0 (at 0-10 cm depth) to 75% (at 30-40 cm depth), associated with a decrease in percentage of water-stable aggregates	Albrecht et al., 2004, cited in Schmidt et al., 2011
	In organic layers of a Canadian aspen forest, in locations with earthworms, N (1.5–0.8%) and especially C concentrations (25.3–9.8%) were strongly reduced, together with C/N ratio (16.7–13.2) and soil pH (6.5–6.1); in brackets: control values vs. values with earthworms. <b>This suggests a shift towards a faster cycling system, resulting in a net loss of C from the soil and turning Northern temperate forests from C sinks into C sources</b>	Eisenhauer et al., 2007
3. Fire-derived carbon	Small charcoal particles from burned plots after one year increased by 21% in 0-1 cm depth. One year later they were concentrated in earthworm casts at the soil surface, after 6.5 years such casts were found at 8 cm depth	Eckmeier et al., 2007
4. Roots	<b>Presence of earthworms in a continuous maize plot in Peruvian Amazonia increased the organic C input from roots by 50%</b>	Jiménez et al., 2006
5. Physical heterogeneity	Up to 50% of soil aggregates in the surface layer of temperate pastures are earthworm casts	Van de Westeringh, 1972
(see also insights no. 2, 3, 6 and 7)	Mull-type forest soil top layers and wooded savanna soils consist almost entirely of earthworm casts	Kubierna, 1953; Lavelle, 1978
	<b>Earthworm inoculation in pastures on young polder soils completely removed within 8-10 years the organic surface layer, incorporated it into deeper layers, creating an A horizon. This affected manifold measures, increasing e.g. grass yield by 10%, root content in 0-15% from 0.38 to 1.31 g dm<sup>-3</sup>, C content in 0-20 cm from 1.78 to 16.9 kg C * 10<sup>3</sup> ha<sup>-1</sup>, and water infiltration capacity from 0.039 to 4.6 m 24 h<sup>-1</sup>. In turn, penetration resistance at 15 cm depth decreased from 35 to 22 kg cm<sup>-2</sup>.</b>	Hoogerkamp et al., 1983
	In average temperature pasture and grasslands, earthworms cast 40-50 t ha <sup>-1</sup> year <sup>-1</sup> on the surface and even more below surface	Lee, 1985
	<b>Passage of a tropical soil through the gut of the invading earthworm <i>Pontoscolex corethrurus</i> reduced macroporosity from 21.7 to 1.6 cm<sup>3</sup> g<sup>-1</sup>, which exceeded the effect of mechanically compacting the same soil at 10<sup>3</sup> kPa (resulting macroporosity: 3 cm<sup>3</sup>g<sup>-1</sup>)</b>	Wilkinson et al., 2009
	After invasion of European earthworms into a Canadian aspen forest a thick layer of their cast material (thickness up to 4 cm) on top of organic layers was developed	Eisenhauer et al., 2007
6. Soil depth	Burrows of anecic earthworms are up to several meters deep and last for many years	Edwards and Bohlen, 1996

\* According to Schmidt et al. (2011)

847 **Table 1.** (continued)

Insight*	Examples	Source
Earthworms		
7. Permafrost and boreal areas	<b>Earthworm invasions in boreal forests completely transformed mor to mull soils and significantly altered the entire plant community</b>	Freligh et al., 2006
8. Soil microorganisms	Earthworms may lower actual microbial activity (by 11-23%) but markedly (by 13-19%) optimize microbial resource utilization.	Scheu et al., 2002
Ants and termites		
2. Humic substances	<b>In a degraded marsh in NE China, ant mounds were CH<sub>4</sub> sinks, contrary to the control soils which were CH<sub>4</sub> sources (-0.39 – -0.19 mg vs. 0.13 – 0.76 m<sup>2</sup> h<sup>-1</sup>)</b>	Wu et al., 2013
5. Physical heterogeneity	Ant and termite mounds can occupy up to 25% of the land surface	Bottinelli et al., 2015
5. Physical heterogeneity and 6. soil depth	<b>Underground nests of leafcutter ants (e.g. <i>Atta</i> spp.) can cover up to 250 m<sup>2</sup> and extend down to 8 m., which is associated with a massive impact on forest vegetation</b>	Correa et al., 2010
Collembola		
8. Soil microorganisms	Grazing by Collembola affected community composition of ectomycorrhizal fungi and on average reduced <sup>14</sup> CO <sub>2</sub> efflux from their mycelia by 14%	Kanters et al., 2015
	Grazing by <i>Protaphorura armata</i> at natural densities on AM fungi disrupted carbon flow from plants to mycorrhiza and its surrounding soil by 32%	Johnson et al., 2005
	<b>The presence of a single Collembola species may enhance microbial biomass by 56%</b>	Filser, 2002
	At elevated temperature, litter decay rates were up to 30% higher due to Collembola grazing	A'Bear et al., 2012
Various or mixed groups		
1. Molecular structure	Microbial grazing by Collembola or enchytraeids alone enhanced leaching of NH <sub>4</sub> <sup>+</sup> or DOC by up to 20% <sup>5</sup>	Filser, 2002
	<b>Feeding by millipedes and snails reduced the content of condensed tannins in three Mediterranean litter species from 9–188 mg g<sup>-1</sup> dry matter to almost zero</b>	Coulis et al., 2009
	Long-term mineralisation of fauna faeces may be slower than the mineralisation of litter from which the faeces were produced. This decrease in decomposition rate corresponds to a decrease in the C:N ratio and in the content of soluble phenols.	Frouz et al., 2015a,b
	Due to stoichiometric constraints, soil animals tend to reduce the C concentration of SOM, but increase N and P availability. About 1.5% of the total N and P in the ingested soil was mineralized during gut passage in humivorous larvae of the scarabaeid beetle <i>Pachnoda ephippiata</i> . In <i>Cubitermes ugandensis</i> termites, the ammonia content of the nest material was about 300-fold higher than that of the parent soil.	Li et al., 2006; Li and Brune, 2007; Ji and Brune, 2006
2. Humic substances	In a laboratory experiment, activity of earthworms, Collembola, enchytraeids and nematodes in coarse sand liberated >40% from the insoluble C pool as compared to the control	Fox et al., 2006
	Radiolabelled proteins and phenolic compounds in litter are faster transformed to humic acids (as revealed by alkaline extraction and acid precipitation) via feces of Bibionidae (Diptera) than from litter not eaten by fauna	Frouz et al., 2011
	The quantitative contribution of invertebrates (mainly beetles and termites) to wood decomposition ranges between 10-20%	Ulyshen, 2014
	<b>Depending on fungal and animal species (Collembola, isopods and nematodes), grazing on fungi colonising wood blocks altered (mostly decreased) their decay rates by more than 100%. Isopods and nematodes had opposite effects in this study.</b>	Crowther et al., 2011

\* According to Schmidt et al. (2011)

**Table 1.** (continued)

Insight*	Examples	Source
Various or mixed groups		
2. Humic substances (continued)	Carbon and nitrogen losses from soil followed by drought and rewetting were substantially affected by microarthropod richness, which explained 42% of the residual variance.	De Vries et al., 2012
5. Physical heterogeneity	<b>Bioturbation rates of soil animal groups typically range between 1 and 5 Mg ha<sup>-1</sup> y<sup>-1</sup> but may reach up to 10 (crayfish, termites), 20 (vertebrates), 50 (earthworms) and &gt; 100 Mg ha<sup>-1</sup> y<sup>-1</sup> (earthworms in some tropical sites), which is equivalent to maximum rates of tectonic uplift</b>	Wilkinson et al., 2009
8. Soil microorganisms	In the course of a 2.5-yr succession, fauna activities (especially of nematodes and mesofauna during the first year, and later of earthworms) accelerated microbial decomposition of clover remains in an arable soil by 43%	Uvarov, 1987
	Depending on vegetation, animal group and climate, soil animals directly or indirectly increased C mineralisation between 1% and 32%. However, intensive grazing by fungal feeders may even reduce C mineralisation	Persson, 1989

\* According to Schmidt et al. (2011)

848  
849

850 **Table 2.** “Insights” (compiled after Schmidt et al., 2011) for future soil organic matter models and  
 851 recommendations for further improvements by implementing effects of soil fauna

SOM modelling element (“Insight”)	Recommendations*
1. Molecular structure	Incorporate the knowledge on the structure of organic substances and element concentrations in faunal casts and excreta in SOM decay rate models. Consider linkage between C and N cycling mediated by fauna. See 8.
2. Humic substances	Add physical and chemical stability of casts, patterns of their microbial colonisation and degradation dynamics. See 1, 3, 5, 6, 7, 8.
3. Fire-derived carbon	Include recolonisation and inoculation potential of surviving soil fauna and adjacent fauna. Initiate studies on the impact of fauna on the fate of black carbon (fragmentation, gut, casts, decomposition, and recolonisation).
4. Roots	Add activity of bioturbators, rhizosphere microbial grazers and root herbivores. See 1, 5, 6, 8.
5. Physical heterogeneity	Consider spatial and physicochemical heterogeneity created by soil fauna, including consequences of soil aggregation and dis-aggregation (e.g. bulk density, infiltration rate, preferential flow, casts). See 1, 2, 6, 8.
6. Soil depth	Incorporate burrowing depth and annual transport rates of bioturbators and animal-induced spatial heterogeneity of old and young carbon in the deep soil. See 5.
7. Permafrost	For warming scenarios, take into account short- and long-term invasion effects, particularly of earthworms and enchytraeids.
8. Soil microorganisms	Add microbial grazer effects, effects on microorganisms during gut passage and faunal impact on C and N coupling. See 1-7.

852 \* Recommendations refer to site-specific keystone groups of animals (dominating in terms of biomass or impact; see  
 853 Fig. 2). Their prevalence is determined by climate, bedrock and land use (e.g. rodents or ants in deserts, earthworms in  
 854 temperate grasslands or microarthropods and enchytraeids in acidic Northern forests).
