21

22 **Abstract.** Acceptability of novel bone char fertilizers depends on their P release but reactions
23 at bone char surfaces and impacts to soil P speciation are insufficiently known. By sequential
24 fractionation and synchrotron-based X-ray absorption near edge structure (XANES)
25 spectroscopy we investigated whether and how the chemical composition of bone char particles
26 has been altered in soil and, consequently, has affected the P speciation of amended soils.
27 Therefore, two different kinds of bone char particles (BC, produced by pyrolysis of degreased
28 animal bone chips at 800 °C and BC^{plus}, a BC enriched with reduced sulfur compounds) were
29 manually separated from the soil at the end of two different experiments: “incubation-leaching”
30 and “ryegrass cultivation”. Sequential P-fractionation of amended soils showed P-enrichment
31 in all fractions as compared to the control. The most P increase between all treatments
32 significantly occurred in the NaOH-P and resin-P fractions in response to BC^{plus} application in
33 both, incubation-leaching and ryegrass cultivation experiments. This increase of the readily
34 available P fraction in BC^{plus} treated soils was confirmed by linear combination fitting (LCF)
35 analysis on P K-edge XANES spectra of BCs particles and amended soils. The proportion of
36 Ca-hydroxyapatite decreased, whereas the proportion of CaHPO₄ increased in BC^{plus} particles
37 after amended soils had been incubated and leached and cropped by ryegrass. Based on P-
38 XANES speciation as determined by LCF analysis, the proportion of inorganic Ca(H₂PO₄)₂
39 increased in amended soils after BC^{plus} application. These results indicated that soil amendment
40 with BC^{plus} particles leads to elevated P concentration and maintains more soluble P species
41 than BC particles even after 230-days of ryegrass cultivation.

42

43

44

45

46 **1 Introduction**

47 At the global scale readily-available sources of phosphorus (P), a crucial macro-nutrient
48 element for agricultural production, are being faced with scarcity and overpricing (Scholz et
49 al., 2013; Van Vuuren et al., 2010). Environmental pollutions frequently arise from their
50 impurities (Cd, U) (Hartley et al., 2013; Kratz et al., 2016), and from over-fertilization (Rubaek
51 et al., 2013). Another problem is the quick formation of stable and inaccessible compounds that
52 limit plant P uptake (Shen et al., 2011). Many recent studies have targeted sustainable
53 agriculture through improving P-availability from applied fertilizers (Delgado et al., 2002;
54 Schröder et al., 2011), increasing P-uptake efficiency from organic and inorganic P-pools in the
55 soil (Kaur and Reddy, 2014) and developing new technologies for P-recycling from human and
56 animal waste (Siebers and Leinweber, 2013; Herzel et al., 2016).

57 As an economically and environmentally attractive example, pyrolyzed animal bone chips
58 branded as “bone char” (BC), a slow-release apatite-based P-fertilizer, have been surface-
59 modified by sulfur (S) compounds to enhance its solubility in neutral to alkaline soils.
60 Incubation and pot experiments confirmed that the surface-modification increased the P-release
61 in an incubation/leaching experiment (Morshedizad et al., 2016). Despite these attempts to raise
62 dissolution and use-efficiency of BC in supplying P for crop requirements, indeed a
63 considerable fraction of applied BC to the soil still remains insoluble in short term and is not
64 taken up by plants over the entire cropping period but this has not yet been explained by a
65 detailed P speciation.

66 Chemical speciation has often been described in terms of analytical identification of chemical
67 species of defined elements and measuring their quantities in the system (Templeton et al.,
68 2000). The precise characterization of variable P species in the soil as a dynamic response to
69 imposed non-equilibrium conditions such as fertilization can support a better understanding of
70 reactivity, stability and particularly plant-accessibility of different P-forms and provide a basis

71 for best management practices. Several techniques such as sequential fractionation (Dieter et
72 al., 2010; Condrón and Newman, 2011), nuclear magnetic resonance (NMR) spectroscopy (Liu
73 et al., 2009; Vestergren et al., 2012; Ahlgren et al., 2013), Raman spectroscopy (Lanfranco,
74 2003; Vogel et al., 2013) and chromatography coupled to mass spectroscopy (De Brabandere
75 et al., 2008; Paraskova et al., 2015) have been developed for P speciation analysis in soil and
76 sediments. Each one of these techniques can offer specific advantages and disadvantages
77 depending on phase and complexity of sample matrixes (Kruse et al., 2015). Complementarily,
78 X-ray absorption near edge structure (XANES) spectroscopy is well-suited to identify various
79 P species through fingerprinting of molecular structures in solid and heterogeneous mediums
80 based on fine feature and position of absorbing edges (Kelly et al., 2008; Kizewski et al., 2011).
81 The advantages of XANES spectroscopy for soil samples have made it a promising technique
82 for direct and *in situ* P-speciation with no pretreatment and minimum sample manipulation
83 (Toor et al., 2006; Kelly et al., 2008).

84 According to the best of our knowledge, no studies have characterized P-speciation changes in
85 BC particles over non-equilibrium conditions in the soil system, and only few investigations
86 have been reported on the P-release from BC and alteration in P-species of the soil. Siebers et
87 al. (2013) investigated K-edge XANES spectroscopy on BC-incubated soil samples and
88 evidenced the increase in extractable Ca- and Mg-phosphate fractions were related to the
89 contribution of hydroxyapatite (HAP) increase after BC application. Accordingly, the objective
90 of this study was to provide applicable information on the fate and alteration of P-species in BC
91 and novel surface modified BC (BC^{plus}) particles and their treated soils under incubation-
92 leaching and ryegrass cultivation practices, using sequential P-fractionation and P-XANES
93 spectroscopy.

94

95 **2 Materials and methods**

96 **2.1 Incubation-leaching experiment**

97 Two types of bone chars (BC, produced by pyrolysis of degreased animal bone chips at 800°C
98 and BC^{plus} as a result of surface-modification of BC through blending with reduced S
99 compounds; characterized in details by Morshedizad et al., 2016) in two particle size fractions
100 (1-2 and 2-4 mm) were incubated with a silt loam soil. The soil was classified as *Dystric*
101 *Cambisol* (FAO) with pH of 4.7 (measured in 0.01 mol L⁻¹ CaCl₂ solution) and total (HNO₃)
102 and available (NH₄NO₃) P-contents of 1.6 g P kg⁻¹ and 14 mg P kg⁻¹, respectively. The BC and
103 BC^{plus} contained total P 149 and 123 g kg⁻¹, total calcium (Ca) 185 and 265 g kg⁻¹, total S 6 and
104 199 g kg⁻¹ and had average of pH_{CaCl2} values 7.8 and 4.9, respectively.

105 The BCs were added to 30 g of air dry soil (<2mm) at the levels of 0 mg P kg⁻¹ soil (control)
106 and 500 mg P kg⁻¹ soil in five replicates, homogenized and packed into glass columns with 10
107 cm length, inner diameter of 2 cm and a P-free filter placed at the bottom to avoid any particle
108 losses. The amended soils were incubated for 70 days at 20 °C in the dark and constant soil
109 moisture between 60-70 % of soil water holding capacity. During the incubation period, the soil
110 columns were leached with three pore volumes of deionized water using a droplet irrigation
111 simulator system in five leaching steps, each one after 1, 5, 13, 34 and 70 days. The P-
112 concentrations in collected leachates were measured using inductively coupled plasma-optical
113 emission spectrometry (ICP-OES). Outcomes of the leaching experiment were described in
114 Morshedizad et al. (2016). After the incubation-leaching experiment, the treated soil samples
115 were carefully removed from the glass columns, air dried and BCs particles were manually
116 separated from the soils very gently. The BCs particles were delicately washed with deionized
117 water to remove adhered soil particles, allowed to dry completely at ambient conditions and
118 finely ground for further analyses.

119

120 **2.2 Pot experiment with annual ryegrass**

121 The same BC and BC^{plus} as described for the incubation-leaching experiment were used in
122 original sizes (mostly between 1 to 5 mm) for P fertilization of annual ryegrass in a pot
123 experiment. The experiment was set-up using an acidic sandy silt soil with available P-content
124 of 24.2 mg P kg⁻¹ and pH of 5.2. The pot experiment was set up by adding BC and BC^{plus} at the
125 levels of 0 mg P kg⁻¹ (control) and 280 mg P kg⁻¹ into the 6 kg of the soil dry matter in each pot
126 and in four replicates arranged in a complete randomized block. After four weeks of incubation
127 at field capacity water content and natural temperature conditions, 30 seeds of annual ryegrass
128 per each pot were sown on 13th of May 2016. The experiment was conducted in a glasshouse
129 under natural air and temperature conditions and the soil moisture was maintained at field
130 capacity during the whole experiment. All other essential nutrients were sequentially added at
131 sufficient levels before seeding and after each six cuts of ryegrass between 23rd of June and 3rd
132 of November 2016. Finally, after the last harvest (7th), plant parts (shoots and roots) were dried
133 at 60 °C and BCs particles were manually separated from the soils, gently washed and
134 subsequently all samples were dried and ground to fine powders for further analyses.

135

136 **2.3 Sequential phosphorus fractionation**

137 Soil samples were sequentially extracted based on chemical solubility in order according to a
138 modified Hedley et al. (1982) procedure. After BC particles detachment, duplicate 0.5 g fine-
139 ground and air-dried soil samples were weighed into 50-mL centrifuge tubes. In summary,
140 chemical P fractionation includes the following steps:

141 1) The mobile and readily available P fraction was extracted with resin strips (saturated in 0.5
142 M NaHCO₃) after 18 hours end-over-end shaking in 30 mL deionized water. The resin strips
143 were separated from solids/solution and washed using 50 mL of 1 M HCl to remove absorbed
144 P. The soil suspension was centrifuged at 2500 × g for 20 minutes and the supernatant was
145 decanted.

146 2) Next, the labile inorganic and organic fractions weakly absorbed to mineral surfaces and
147 some microbial P were extracted with 30 mL of 0.5 M NaHCO₃, 18 hours end-over-end shaking
148 and centrifugation at 2500 × g for 20 minutes. The supernatant was filtered and collected for
149 measurements.

150 3) The inorganic P adsorbed and bound to Al- and Fe- oxide minerals and organic P from humic
151 substances were extracted using 30 mL of 0.1 M NaOH solution and repeating the second step
152 procedure as described above.

153 4) The relatively insoluble fraction of P bound to Ca and Mg minerals and apatite was extracted
154 with 30 mL of 1 M HCl in the same way as for the previous steps.

155 Total P concentrations (P_t) and inorganic P (P_i) in all extracts were measured by ICP-OES and
156 colorimetrically (molybdenum blue method; Murphy and Riley, 1962), respectively. The
157 organic P (P_o) concentrations were calculated by $P_t - P_i$.

158

159 **2.4 Phosphorus K-edge XANES analysis**

160 The XANES data collection for characterizing P-species in all soil samples and BCs particles
161 was acquired at the Synchrotron Light Research Institute (SLRI) in Nakhon Ratchasima,
162 Thailand, on the beamline 8 (BL8) of the electron storage ring with a covering photon energy
163 from 1.25 to 10 KeV, electron energy operated at 1.2 GeV and beam current of 80-150 mA
164 (Klysubun et al., 2012). The P K-edge XANES spectra were collected from dried and very
165 finely ground particulate samples which had been diluted to lower P concentrations than <10
166 mg P kg⁻¹ with SiO₂ powder (to eliminate self absorption effects; Prietzel et al., 2013), again
167 ground in agate stone mini-mortar and spread uniformly as a thin layer on P-free kapton tape
168 (Lanmar Inc., Northbrook, IL, USA). Data collection was operated in standard conditions
169 comprising the energy calibration by standard pure elemental P and allocating the reference
170 energy (E_0) at 2145.5 eV using the maximum peak of spectrum. All spectra were recorded at

171 photon energies between 2045.5 and 2495.5 eV in step sizes of 5 eV (2045.5 to 2105.5 eV and
172 2245.5 to 2495.5 eV), 1 eV (2105.5 to 2135.5 eV and 2195.5 to 2245.5 eV) and 0.25 eV (2135.5
173 to 2195.5 eV) with a 13-channel germanium detector. At least three scans were collected and
174 averaged for each sample.

175 The P-XANES spectra were normalized and after merging replicates, a linear combination
176 fitting (LCF) was performed using the ATHENA software package (Ravel and Newville, 2005).
177 The following set of reference P *K*-edge XANES spectra, all recorded in SLRI under the same
178 adjustments by Werner and Prietzel (2015) and Prietzel et al. (2016), were used for fitting and
179 calculations; Ca-, Al- and Fe-phytate, non-crystalline and crystalline AlPO₄, non-crystalline
180 and crystalline FePO₄·2H₂O, Ca-hydroxyapatite (Ca₅(OH)(PO₄)₃), inositol hexakisphosphate
181 (IHP), ferrihydrite-IHP, montmorillonite-Al-IHP, soil organic matter (SOM)-Al-IHP,
182 ferrihydrite-orthophosphate, montmorillonite-Al-orthophosphate, SOM-Al-orthophosphate,
183 bohemite-IHP, bohemite-orthophosphate, CaHPO₄, Ca(H₂PO₄)₂ and MgHPO₄. To select the
184 best possible combination fit between the sample spectrum and the P-reference spectra, the
185 lowest reduced chi value (χ^2) and *R*-factor were chosen.

186

187 **3 Results**

188 **3.1 Effect of BCs on sequentially extracted P after incubation-leaching**

189 After 70 days of incubation-leaching, the sequential P-fractionation of amended soils showed
190 variations in the amount and distribution of various P-fractions between different treatments
191 (Table 1). For all treatments, NaOH extracted the majority of fractionated P (62.4 to 66.5 % of
192 total fractionated P), followed by the labile P fraction (NaHCO₃, 19.2 to 20.0 %), HCl-P (9.5
193 to 13.9 %) and the readily available P (resin strips, 4.1 to 4.8 %). The BCs addition increased
194 the soil P pools although the difference was significant only for the BC^{plus}_{1-2 mm} and BC_{1-2 mm}
195 treatments. The largest increase in total fractionated P_t (resin-P_t + NaHCO₃-P_t + NaOH-P_t +

196 HCl-P_t) occurred in BC^{plus}_{1-2 mm} (133.8 mg P kg⁻¹ soil) followed by BC_{1-2 mm} (118.6 mg P kg⁻¹
197 soil), BC_{2-4 mm} (67.1 mg P kg⁻¹ soil) and BC^{plus}_{2-4 mm} (35.7 mg P kg⁻¹ soil), compared to the
198 control soil. The proportion of P-enrichment in each fraction varied between different
199 treatments in the order NaOH-P > HCl-P > NaHCO₃-P > resin-P for BC^{plus}_{1-2 mm} and BC^{plus}_{2-4 mm}.
200 For the BC_{1-2 mm} and BC_{2-4 mm} treatment the order was HCl-P > NaOH-P > NaHCO₃-P >
201 resin-P. In all treatments, the P_i proportions in each of the P fractions were greater than the P_o
202 proportions. Compared to the control soil, the most P_i increase was observed in NaOH-P_i and
203 resin-P_i in response to BC^{plus}_{1-2 mm} application.

204

205

INSERT Table 1 HERE

206

207 In leachate samples, the two particle sizes of BC and BC^{plus} gave a significant rise in P-
208 concentration after 1, 5, 13, 34 and 70 days of incubation (Morshedizad and Leinweber, 2017).
209 Results of whole incubation-leaching period revealed that the averaged increase in
210 accumulative leached P concentrations were 4.66 mg P kg⁻¹ soil (BC_{1-2mm}), 4.21 mg P kg⁻¹ soil
211 (BC_{2-4mm}), 3.68 mg P kg⁻¹ soil (BC^{plus}_{1-2mm}) and 3.19 mg P kg⁻¹ soil (BC^{plus}_{2-4mm}) compared to
212 the control soil. Soil pH increased in BC treatments after 70 days of incubation-leaching
213 whereas BC^{plus} amendments had an acidifying effect. Soil pH levels of BC_{1-2mm} and BC_{2-4mm}
214 increased by 0.07 and 0.05 units and decreased for BC^{plus}_{1-2mm} and BC^{plus}_{2-4mm} treatments by
215 0.21 and 0.15 units compared to unamended control soil (pH = 5.06).

216

217 **3.2 Effect of BCs on sequentially extracted P after ryegrass cropping**

218 Sequentially extracted P fractions in soil varied between different treatments after 230 days of
219 ryegrass cropping (Table 1). In all treatments (control, BC and BC^{plus}), the largest P pool was
220 mainly associated with Al- and Fe-oxide minerals and humic substances (NaOH-P, 65.0 to 67.5

221 % of total fractionated P) followed by the $\text{NaHCO}_3\text{-P}$ (18.2 to 19.0 %), HCl-P (11.5 to 12.6 %)
222 and resin-P (2.2 to 3.4 %) fractions. Both BC and BC^{plus} amendments led to enrichments of P
223 fractions, except for the readily available and labile inorganic P concentrations in the BC
224 treatment. The maximum increase of total fractionated P was obtained in BC^{plus} treatment (37.6
225 mg P kg^{-1} soil). In comparison to incubation-leaching results, a similar sequence was observed
226 for the order of increasing magnitude of P fractions in response to BC and BC^{plus} amendments
227 ($\text{NaOH-P} > \text{NaHCO}_3\text{-P} > \text{HCl-P} > \text{resin-P}$). However, for BC treatment, the total P extracted
228 by resin strips was lowered in comparison with the control. In the control and BC treatments,
229 P_0 was the predominant form in NaOH-P and $\text{NaHCO}_3\text{-P}$ fractions while for BC^{plus} it was only
230 in the NaOH-P fraction. Each P fraction was highest under BC^{plus} application, except for
231 $\text{NaHCO}_3\text{-P}_0$ of BC treatment. Additionally, a significant increase in P concentration was
232 obtained only in resin- P_i and NaOH-P_i fractions of the BC^{plus} treated soil (Table 1).
233 Separately, the effect of BC and BC^{plus} application on ryegrass yield parameters was examined
234 in the 230-days pot experiment. The results indicated that P uptake, ryegrass yield and apparent
235 nutrient recovery efficiency (ANR) of BC^{plus} treatments exceeded that of BC and control
236 treatments and increased to values comparable with triple super phosphate (TSP) fertilizer.
237 Addition of BC and BC^{plus} did not significantly change soil pH, although likely occurrence of
238 local acidification around BC^{plus} particles lowered soil pH by 0.01 to 0.05 units (insignificant)
239 compared to BC treatments at harvest time (Zimmer, D. and Panten, K., personal
240 communication).

241

242 3.3 XANES analysis of BCs particles

243 All spectra from BCs were characterized by an intense white-line peak, post-edge position and
244 without a distinct pre-edge which corresponded to calcium phosphate compounds including Ca-
245 hydroxyapatite, dicalcium phosphate (CaHPO_4) and Ca-phytate (Fig. 1). The P K-edge XANES

246 results indicated no obvious alterations in spectral features of BCs particles after the incubation-
247 leaching experiment. After 70-days of incubation-leaching, the BC spectra were shifted towards
248 Ca-hydroxyapatite, and this was more pronounced for the 2-4 mm than for the 1-2 mm BC-
249 particles. The opposite trend was the case for BC^{plus} particles where the white-line signal
250 intensity decreased after incubation-leaching period and the post-edge of spectra tended more
251 to dicalcium phosphate. This effect was stronger for BC^{plus}-particle size reduction from 2-4 mm
252 to 1-2 mm.

253

254

INSERT Figure 1 HERE

255

256 To quantify the P speciation of BC and BC^{plus} particles, LCF analyses using all possible
257 combinations were performed on all P *K*-edge XANES spectra (Table 2). The fitting results
258 indicated that untreated BC and BC^{plus} particles before the experiment contained on average 61
259 and 60 % Ca-hydroxyapatite, 22 and 30 % CaHPO₄ and 18 and 10 % Ca-phytate. After 70-days
260 of incubation-leaching, the proportion of Ca-hydroxyapatite increased to the average of 80 %
261 in BC while it remained unchanged in BC^{plus} particles. The CaHPO₄ proportion increased in
262 BC^{plus} particles to the average of 34 % whereas the lower content was assigned in the spectra
263 of BC particles accounting for 10 % of total P species. Moreover, the Ca-phytate proportion
264 decreased slightly in BC and BC^{plus} particles from about 18 and 10 % to averages of 11 and 7
265 %, respectively.

266

267

INSERT Table 2 HERE

268

269 Spectra of BC and BC^{plus} particles, before and after 230-days of ryegrass cultivation, were
270 characterized by a sharp white-line followed by a shoulder and then a post-edge feature between

271 2160 and 2175 eV which was divided into two peaks (Fig. 2). These features were most similar
272 to P *K*-edge XANES spectra of Ca-hydroxyapatite, CaHPO₄ and Ca-phytate standard
273 compounds. Treated BC particles had a white-line with higher intensity which appeared more
274 similar to the Ca-hydroxyapatite spectrum. In contrast, BC^{plus} particles under ryegrass
275 cultivation showed a weaker white-line exhibiting the shoulder and post-edge feature more
276 comparable to the CaHPO₄ spectrum.

277

278 **INSERT Figure 2 HERE**

279

280 Some differences in proportions of P species observed between BCs particles before and after
281 the cropping period in ryegrass pot experiment are presented in Table 3. The LCF results
282 revealed overall contributions of 63 and 70 % Ca-hydroxyapatite, 29 and 29 % CaHPO₄ and 8
283 and 1 % Ca-phytate in the original BC and BC^{plus}, respectively. After the cropping period, the
284 percentage of Ca-hydroxyapatite was increased in BC particles. In the BC^{plus} treatment, the
285 percentage of CaHPO₄ increased from 29 to 43, while the percentage of Ca-hydroxyapatite was
286 reduced from 70 to 49 %. The Ca-phytate proportion remained unchanged in BC particles while
287 that of BC^{plus} increased from 1 to 8 % after the ryegrass cultivation period.

288

289 **INSERT Table 3 HERE**

290

291 **3.4 XANES analysis of soil samples**

292 The P *K*-edge XANES spectra of soil samples from the incubation-leaching experiment showed
293 two dominant features including 1) a strong white-line lacking pre-edge and shoulder and 2) a
294 tailed post-edge feature (Fig. 3). The most similarity to these features was seen in XANES
295 spectra of amorphous AlPO₄, FePO₄ and SOM-Al-IHP compounds. Distinct differences

296 appeared between the control and treated soil with BC^{plus}, not with BC treatments. This was
297 reflected by slightly lower intensities of both white-line and post-edge features.

298

299 **INSERT Figure 3 HERE**

300

301 The P species of treated soils in the incubation-leaching experiment were determined by LCF
302 analysis to select at most four reference compounds in combinatorics of all possible fitting
303 combinations (Table 4). The fitting results indicated that P in the control soil and BC treatments
304 occurred dominantly as AlPO₄ amorphous ($\approx 40\%$), FePO₄ ($\approx 30\%$) and SOM-Al-IHP (≈ 20
305 %) compounds. In BC^{plus} treated soils, the average proportion of amorphous AlPO₄ decreased
306 to 26 % and instead, Ca(H₂PO₄)₂ was identified with an average of 25 % which did not appear
307 in the control and BC treatments. The LCF results showed that the soil treated with BC^{plus} had
308 no detectable Ca-hydroxyapatite which was found in the control and BC treatments.

309

310 **INSERT Table 4 HERE**

311

312 The XANES spectra recorded from treated soil samples in the ryegrass pot experiment showed
313 the presence of an intense white-line in the energy range of 2152 to 2158 eV and a stretched
314 post-edge feature approximately from 2165 to 2178 eV (Fig. 4). Decreases in white-line and
315 post-edge intensities of the soil samples appeared as an effect of BC^{plus} application. Visual
316 inspection of P *K*-edge spectra revealed no indication of specific alteration in spectral features
317 in response to the BC treatment.

318

319 **INSERT Figure 4 HERE**

320

321 Amorphous AlPO_4 was characterized by LCF analysis as dominant component ($\approx 35\%$) in all
322 treated soil samples from the ryegrass pot experiment (Table 5). The second major P form in
323 the control soil was IHP (29 %) followed by Ca-phytate (27 %), with the latter also as
324 pronounced as that observed for BC and BC^{plus} treatments. All treated soils varied in
325 proportions of free or bound IHP forms. The Mont-Al-PO_4 and $\text{Ca}(\text{H}_2\text{PO}_4)_2$ compounds were
326 only assigned in the control and BC^{plus} treatments, respectively.

327

328 **INSERT Table 5 HERE**

329

330

331 **4 Discussion**332 **4.1 P availability as revealed by sequential fractionation**

333 The sequence of P distribution between sequentially extracted P-fractions was in accordance
334 with findings by many studies (Cross and Schlesinger, 1995; McDowell and Stewart, 2006;
335 Hashimoto and Watanabe, 2014), reflecting the general status of different P-pools in acidic
336 soils. The results indicated that the largest P proportion was found in the NaOH fraction
337 reflecting P fixed to Fe- and Al-oxides as followed by the NaHCO_3 -P fraction assigned to
338 weakly P absorbed on crystalline Fe- and Al-oxides or surface of minerals. Guo et al. (2000)
339 reported that the NaOH-P fraction may support the labile NaHCO_3 -P fraction as a buffering P-
340 pool in highly weathered and acidic soils. According to soil pH values (4.7 and 5.2), the larger
341 proportions of NaHCO_3 -P even than HCl-P can be explained by the abundance and positive
342 loadings of Fe- and Al-oxides and a scarcity of Ca and Mg minerals or soluble ions. As
343 expected, the lowest P proportions were found in the mobile and readily available P fraction
344 extracted by resin strips in agreement to many comparable studies (Cross and Schlesinger,
345 1995; Bauchemin et al., 2003; Sharpley et al., 2004; Siebers et al., 2013). Among the two soils

346 which were used in the two different experiments, the most inorganic P fractions were achieved
347 in the soil after incubation-leaching experiment, while the organic P forms were considerably
348 more abundant in the soil samples after ryegrass cultivation (Table 1). These differences may
349 be due to the microbial activities in the rhizosphere of grasses and transformation of P_i to more
350 stable P_o fractions during longer plant cultivation period (230 days) than in the non-cropped
351 incubation/leaching experiment (70 days).

352 In general, all P fraction concentrations were elevated by adding BC and BC^{plus} particles which
353 appeared to follow the same pattern in both soils under two different experimental conditions.
354 However, significant differences were found only between the control and BC^{plus} treated soils
355 (1-2 mm in the incubation-leaching experiment) for the resin-P and NaOH-P fractions. Since
356 the BCs particles were separated from the soils before chemical analysis, it was expected that
357 partly dissolved BCs would have a limited impact on different P-fractions rather than totally
358 ground and mixed BCs. This is consistent with the study of Siebers et al. (2013) according to
359 which the BC application ($<90 \mu m$ BC thoroughly mixed to soil) significantly increased the
360 insoluble P proportion (H_2SO_4 -P). Additionally, our study confirmed previous findings
361 concerning the effect of particle sizes on the P release from BCs (Morshedizad and Leinweber,
362 2017) and consequently the P status of treated soils (Ma and Matsunaka, 2013). Sequentially
363 extracted P contents increased with decreasing size of BC particles whereby BC^{plus} treatments
364 appeared more dependent on particle size than BC treatments. The results of sequential P
365 fractionation of BC^{plus} treatments indicated that the P increase was more pronounced for P fixed
366 to Al- and Fe-oxides (NaOH-P) than other fractions, whereas for BC treatments the largest
367 increase occurred in P bound to Ca and Mg minerals (HCl-P). It seems that local pH changes
368 in soil associated with BC and BC^{plus} amendments could eventually lead to a different
369 distribution of released P into differently soluble or insoluble P-pools which are generally
370 controlled by pH (Arai and Sparks, 2007).

371

372 **4.2 P speciation of BCs particles by XANES**

373 The predominance of Ca-hydroxyapatite in BCs as evidenced by P *K*-edge XANES analysis is
374 consistent with findings reported by previous studies (Warren et al., 2009; Siebers et al., 2013).

375 The mineral phase of bone consists mainly of hydroxyapatite, and its contribution to bone and
376 bone char compositions depends on species and the age of animals (Wu et al., 2003) and
377 carbonization temperature and residence time (Novotny et al., 2012). Bone crystallinity might
378 be improved through structural modifications on poorly crystalline fresh bone samples (such as
379 mineral maturity over periods of time or intensive carbonization) which can result in increased
380 proportions of hydroxyapatite and accordingly a decrease in P solubility (Novotny et al., 2012).

381 Based on LC fittings, the second major component of BCs particles was CaHPO₄, in good
382 agreement with the results of Rajendran et al. (2013) who indicated the heated bones at 400 °C
383 contained some more soluble phosphates such as CaHPO₄ and CaH₂PO₄ in addition to the
384 hydroxyapatite fraction. The authors reported that spectra of calcined bone samples at 700 °C
385 had white-line at 2154 eV and two post-edge peaks at 2162 eV and 2169 eV with no pre-edge
386 peaks and appeared similar to CaHPO₄ and CaH₂PO₄ spectra. Our LCF also assigned Ca-
387 phytate in BCs samples which seems to be controversial as a component of animal bone
388 materials. The P *K*-edge spectrum of Ca-phytate is very similar to other Ca-bound P compounds
389 with a distinct white-line and lack of a pre-edge feature, although it is likely distinguishable due
390 to specific shape of white-line tailing and absence of post-edge signal at 2164 eV (Prietz et
391 al., 2016). Moreover, some inaccuracies in LCF estimations have to be considered because of
392 1) uncertainty in speciation of organic P forms by *K*-edge XANES, 2) lack of reference
393 compounds representing all P forms in BCs and 3) smaller Ca-phytate proportions than
394 proposed 10 to 15 % of P_i as detection limit for reliable XANES fittings (Beauchemin et al.,
395 2003).

396 In both experiments, incubation/leaching and ryegrass cropping, changes in proportions of Ca-
397 hydroxyapatite and CaHPO_4 in BC particles followed an opposite trend than in BC^{plus} particles.
398 After placement of BC particles in the soil, Ca-phosphate seemed to be released gradually over
399 time which provides a locally lime-saturated condition. Due to elevated pH surrounding the BC
400 particles, dissolved P can be resorbed to maintain solubility and the Ca-P equilibrium constant
401 which likely resulted in a decreased proportion of soluble CaHPO_4 and possibly the
402 transformation into the relatively insoluble Ca-hydroxyapatite fraction. In contrast, if BC^{plus}
403 particles were applied to soils, larger proportions of CaHPO_4 at the expense of Ca-
404 hydroxyapatite could be explained by soil acidification through the microbial oxidation of
405 released S. This effect was more pronounced over the longer time period in the ryegrass
406 cropping pot experiment, favoring a greater CaHPO_4 than Ca-hydroxyapatite fraction. This
407 implies that BC^{plus} can actively supply P with predominance of soluble over insoluble P forms
408 in the long-term and, thus, meet crop requirements. In general, the P composition changes in
409 BCs particles revealed by K-edge XANES can explain overall trends in soils to some extent
410 considering the amount of dissolved and added BCs to the soils.

411

412 **4.3 P speciation of treated soils by XANES**

413 Differences between characteristics of two soils, dissimilar mechanisms of incubation-leaching
414 and plant uptake besides different experiment time durations complicate the joint interpretation
415 of the P-XANES data. In unfertilized soil of the incubation-leaching experiment, the
416 proportions of P species followed the order $\text{AlPO}_4 > \text{FePO}_4 > \text{SOM-Al-IHP} > \text{Ca-}$
417 hydroxyapatite which did not vary despite partial changes in some proportions after application
418 of both size fractions of BC particles. In general, these results concur with the findings by
419 Siebers et al. (2013) that Ca-hydroxyapatite proportion was slightly increased by BC
420 application. This could be attributed to irreversibly mixing finely-ground BC to the soil samples

421 whereas in the present experiments the BC particles were separated from the soils before P
422 speciation. Furthermore, these XANES data (Table 4 and Table 5) are in agreement with
423 sequential P fractionation results (Table 1) which indicated the dominance of inorganic over
424 organic P forms and showed the P fractions almost unchanged after BC application.
425 Implications of low solubility of BC particles observed in this work are consistent with previous
426 studies showing a slow release P from BCs (Warren et al., 2009; Siebers et al., 2013;
427 Morshedizad et al., 2016). Besides reducing the AlPO_4 and Ca-hydroxyapatite proportions,
428 BC^{plus} particles introduced highly soluble $\text{Ca}(\text{H}_2\text{PO}_4)_2$ to soils in the incubation-leaching
429 experiment. These results imply that considerable changes in P speciation were more attributed
430 to pH reductions and, accordingly, leaching out solubilized P-forms compared with P
431 enrichment by BC^{plus} dissolution. This is in line with Sato et al. (2005) who found that
432 increasing soil pH in a naturally acidic soil (pH = 4.32) was an effective approach to minimize
433 P leaching, while pH decrease resulted in transformation of stable to soluble and more leachable
434 P species. Regarding to the XANES results of ryegrass cultivation experiment (Table 5), the
435 effect of BC^{plus} treatment can be explained better. In control soil, the presence of AlPO_4 and
436 increasing abundance of organic P-forms (Ca-phytate and IHP compounds) (Table 5) were
437 consistent with the appearance of NaOH-P and HCl-P fractions by sequential extraction (Table
438 1). In the BC treatment the proportions of AlPO_4 and Ca-phytate did not change compared to
439 the control but the contribution of organic P increased by Mont-Al-IHP formation. The stability
440 of different P fractions can be favored by the pH effect (Gustafsson et al., 2012) likewise the
441 dependence of BC particles solubility on the soil pH (Siebers et al., 2013). In agreement with
442 incubation-leaching results (Table 4), $\text{Ca}(\text{H}_2\text{PO}_4)_2$ was detected as a result of BC^{plus} amendment
443 even though similar proportions of AlPO_4 and Ca-phytate were observed between the control
444 and BC^{plus} treatment. The results of sequential P fractionation and XANES analyses on two

445 different practices presented here demonstrated that surface modification of BC particles
446 effectively improved soluble P fractions in BC^{plus} particles and, consequently, in amended soils.
447

448 **5 Conclusions**

449 In the present study, the P speciation by a sequential P fractionation and P *K*-edge XANES
450 spectroscopy revealed the noticeable alteration in the P-pools of treated soil samples. Results
451 of incubation-leaching and ryegrass cultivation experiments indicated that BC^{plus} produced by
452 surface-modification of BC through adding S compounds providing more soluble and plant-
453 available P fraction than BCs during the growth season. The S oxidation and thereby the soil
454 pH decrease seems to stimulate the P release from BC^{plus} particles. The P *K*-edge XANES
455 analysis of BC^{plus} particles revealed more soluble CaHPO₄ than BC particles at the expense of
456 Ca-hydroxyapatite. This was associated with Ca(H₂PO₄)₂ addition to amended soils, as
457 identified by sequential P fractionation and XANES analyses. Future studies will be directed to
458 validate the beneficial effects of BC^{plus} at the field scale with different soils and to optimize the
459 surface modification of BCs.

460

461 **Data availability.** All compiled data of this study are published in figures and tables. Detailed
462 primary data including the incubation-leaching and ryegrass cultivation results and the acquired
463 XANES spectra will be saved and published in the BonaRes Data Center
464 (<https://www.bonares.de/research-data>) and get the BonaRes DOI prefix (10.20387).

465

466 **Competing interests.** The authors declare that they have no conflict of interest.

467

468 **Acknowledgments.** We are grateful to the technician team and all staff at the Beamline 8
469 of SLRI for their help and assistance associated to XANES spectra acquisitions. The authors

470 are appreciative to Prof. J. Prietzel (Department of Soil Science, Technical University of
471 Munich) for providing the P reference spectra and invaluable comments that improved our
472 research. M. Morshedizad acknowledges a Ph.D. grant from the Federal State of Mecklenburg,
473 Western Pommerania in Germany. Parts of this work were funded by the German Federal
474 Ministry of Education and Research (BMBF) through the BonaRes-Project InnoSoilPhos (No.
475 031A558).
