

1 Dear Asmeret,

2 Dear Editors,

3 Thank you very much for the positive decision on our paper.

4 We corrected the last bits and pieces according to your recommendation.

5 We agree with you that the use of terms need to be consistent throughout
6 the manuscript. However, we do not agree with the use of the term
7 concentration for SOC in g/kg. According to the international definitions of
8 units “concentration” refers to mass per volume. Therefore, we propose to
9 keep the term “content” for a mass fraction of SOC in soils since this value
10 does not refer to a fixed volume.

11

12 We hope you can accept this since we checked that the terms are used
13 consistently throughout the manuscript.

14

15 Best regards,

16 Cora Vos and Axel Don

28

29 **Abstract**

30 Atmospheric carbon dioxide levels can be mitigated by sequestering carbon in the soil. Sequestration
31 can be facilitated by agricultural management, but its influence is not the same on all soil carbon
32 pools, as labile pools with high turnover may be accumulated much faster, but are also more
33 vulnerable to losses. The aims of this study were to 1) assess how soil organic carbon (SOC) is
34 distributed among SOC fractions on national scale in Germany, 2) identify factors influencing this
35 distribution and 3) identify regions with high vulnerability to SOC losses. The SOC content and
36 proportion of two different SOC fractions were estimated for more than 2500 mineral topsoils (<87 g
37 kg⁻¹ SOC) covering Germany, using near-infrared reflectance spectroscopy. Drivers of the spatial
38 variability in SOC fractions were determined using the machine learning algorithm cforest. The SOC
39 content and proportions of fractions were predicted with good accuracy (SOC content: R²=0.87-0.90,
40 SOC proportions R²=0.83, ratio of performance to deviation (RPD) 2.4-3.2). Main explanatory
41 variables for distribution of SOC among the fractions were soil texture, bulk soil C/N ratio, total SOC
42 content and pH. For some regions, the drivers were linked to the land-use history of the sites.

43 Arable topsoils in central and southern Germany were found to contain the highest proportions and
44 contents of stable SOC fractions, and therefore have the lowest vulnerability to SOC losses. North-
45 Western Germany contains an area of sandy soils with unusually high SOC contents and high
46 proportions of light SOC fractions, which are commonly regarded as representing a labile carbon
47 pool. This is true for the former peat soils in this area, which have already lost and are at high risk of
48 losing high proportions of their SOC stocks. Those “black sands” can, however, also contain high
49 amounts of stable SOC due to former heathland vegetation, and need to be treated and discussed
50 separately from non-black sand ~~‘normal’~~ agricultural soils. Overall, it was estimated that, in large
51 areas all over Germany, over 30% of is stored in easily mineralisable forms. Thus, SOC-conserving
52 management of arable soils in these regions is of great importance.

53

54 **1 Introduction**

55 There is increasing interest in soil organic carbon (SOC) in agricultural soils, as it contributes to soil
56 fertility and also to mitigation of climate change when organic carbon sequestration is enhanced
57 (Post and Kwon, 2000). In agricultural systems the pathway of atmospheric carbon to SOC is
58 controlled by land-use and agronomic management. However, SOC comprises a large range of
59 compounds, ranging from recently added organic matter, such as root litter and exudates, to highly
60 condensed and transformed organic matter that may even be derived from the geogenic parent
61 material. These different compound classes are stabilised in different ways and therefore have
62 different turnover times (Lehmann and Kleber, 2015). Although SOC is now considered as having a
63 continuum of turnover times, it is mostly described and modelled as consisting of different pools that
64 vary in their turnover time (e.g. labile pool, intermediate pool and stabilised pool). The effects of
65 land-use and management are not the same for all soil organic matter compounds, they differ
66 between SOC pools. Chimento et al. (2016) for example, found that cultivation of perennial woody
67 bioenergy crops increased SOC stocks compared to other bioenergy crops, but the new SOC
68 accumulated only in the light and presumably labile particulate organic matter (POM) fraction.
69 Poepflau and Don (2013a), on the other hand, found that cropland sites that were changed to
70 grassland also sequestered new SOC, but mainly in the more stable fractions. Therefore, the different
71 SOC pools need to be assessed separately from the bulk SOC when discussing the influence of land-
72 use and management on stabilisation and storage of SOC.

73 One method for experimental quantification of the distribution of SOC among different SOC pools is
74 fractionation. Various fractionation procedures for quantifying SOC fractions have been developed,
75 mostly aiming at isolating fractions with differing turnover times (Poepflau *et al.*, in review,
76 Zimmermann et al., 2007a). Determining the distribution of SOC among fractions with assumedly
77 different turnover times is one step towards understanding the factors influencing SOC stabilisation.
78 All methods for carbon fractionation are quite laborious, time-consuming and therefore expensive,
79 and not feasible for large datasets. Therefore, few studies exist on SOC fractions at regional scale,

80 indicating a need for development of more efficient methods to predict carbon fractions in
81 assessment of large datasets. Near-infrared reflectance spectroscopy (NIRS) and mid-infrared
82 spectroscopy (MIRS), in combination with chemometric methods, have been applied successfully to
83 predict carbon fractions (Zimmermann *et al.*, 2007b; Baldock *et al.*, 2013; Cozzolino & Moro, 2006;
84 Reeves *et al.*, 2006). Thus, since prediction of SOC fractions has been demonstrated to be possible
85 using spectroscopic methods, it should also be possible to go beyond small datasets at field scale in
86 order to examine how SOC fractions are distributed regionally and the factors that drive this
87 distribution.

88 Some impact factors are consistently reported as being important at site scale for the distribution of
89 SOC among different fractions or pools, one of which is land-use. For Western European croplands
90 and grasslands, it was shown that a similarly high share of bulk SOC is attributed to fractions
91 regarded as stable, while in forest soils, a higher proportion of SOC is attributed to more labile SOC
92 fractions (John *et al.*, 2005; Helfrich *et al.*, 2006; Wiesmeier *et al.*, 2014). Tillage can also have an
93 impact on SOC pools, as some studies report higher levels of bulk SOC under no-till conditions
94 compared with conventional tillage, with the majority of this increase occurring in the more labile
95 carbon pools (Chan *et al.*, 2002; Devine *et al.*, 2014; Liu *et al.*, 2014). This may, however, be just an
96 effect of carbon redistribution in the soil and not lead to a net increase of SOC (Baker *et al.*, 2007;
97 Luo *et al.*, 2010).

98 Fewer studies have examined the SOC distribution into fractions at regional scale and even fewer
99 have examined factors affecting the proportions of SOC distributed among different fractions or
100 pools. Wiesmeier *et al.* (2014) determined the distribution of SOC fractions among 99 Bavarian soils
101 under different land-uses using the fractionation scheme devised by Zimmermann *et al.* (2007a),
102 which is a combination of particle size and density fractionation. They found that approximately 90%
103 of the bulk SOC in cropland and grassland soils was distributed in intermediate or stabilised SOC
104 pools, while this was only true for 60% of the SOC found in forest soils. Therefore, those authors
105 suggested that Bavarian soils under cropland and grassland are more suitable for long-term

106 sequestration of additional SOC than soils under forest. They also examined controlling factors for
107 the SOC distribution among fractions in the different land-uses (Wiesmeier *et al.*, 2014). Correlation
108 analyses suggested that the intermediate SOC pools in croplands and grasslands were significantly
109 correlated to soil moisture, but none of the functional SOC pools were influenced by temperature or
110 precipitation. The particulate organic matter (POM) fraction of soils under grasslands and croplands
111 was not significantly related to any environmental factor in that study (Wiesmeier *et al.*, 2014).
112 Poeplau & Don (2013a) conducted a study on 24 sites in Europe and found that SOC fractions
113 differed in their degree of sensitivity to land-use change (LUC), with the sensitivity declining with
114 increasing stability in the SOC fractions. Their results indicated that afforestation of cropland shifts
115 SOC from the more stable to the more labile fractions, while the conversion from cropland to
116 grassland the newly sequestered SOC is stored in the intermediate to stable pools. Rabbi *et al.* (2014)
117 examined the relationships between land-use, management, climate and soil properties and the
118 stock of three SOC fractions for soils in south-eastern Australia, and observed a high impact of
119 climate and site-specific factors (rainfall, silicon content, soil pH, latitude) and only a minor influence
120 of land-use. The dominance of site and climate variables as impact factors in that region may
121 primarily be due to the wide range of site conditions in the area studied.

122 If the regional distribution of SOC fractions can be predicted using a combination of fractionation
123 methods and NIRS and if relevant drivers for this distribution can be found, it should be possible to
124 identify regions in Germany in which soils are most vulnerable to carbon losses. Some carbon
125 fractions are commonly assumed to be more labile than others because they apparently have lower
126 turnover times in the soil. The question is if it can simply be assumed that soils that contain a high
127 percentage of those “labile” fractions are more vulnerable to carbon losses than others. On the one
128 hand, it should be noted that for the assessment of vulnerability to carbon losses, not only the
129 distribution of the fractions should play a role, but also the absolute amounts of carbon within the
130 fractions. This is important as some soils may have stored a high percentage of SOC in a labile form,
131 but the absolute amount of this SOC may be very low and thus less relevant in terms of climate

132 change mitigation than a small percentage of light fraction that is lost from a soil rich in SOC. On the
133 other hand, there are several regions in north-Western Europe and also in northern Germany where
134 the soils exhibit unusually high SOC content while having a high sand and low clay content (Sleutel *et*
135 *al.*, 2011). These so called ‘black sands’ have a poor capacity to stabilise SOC by binding onto mineral
136 surfaces, and therefore most SOC is present in the form of POM. A great part of this land surface in
137 northern Germany was covered by heathland and peatland until the end of the 18th century and
138 those soils may behave different than other soils in terms of SOC storage and the vulnerability to
139 carbon losses may not generally be definable via dividing SOC into fractions by density fractionation.

140 The present study is part of the German Agricultural Soil Inventory. A set of 145 topsoil samples,
141 representative of German agricultural soils, was fractionated and used to calibrate NIRS predictions
142 of the constituent fractions for > 2500 sites with mineral soils all over Germany. Additional climate,
143 management and geographical data were gathered for all sites and a machine learning algorithm was
144 employed to clarify which factors influence the distribution of the carbon fractions. In this paper we
145 therefore aim to answer the following research questions:

- 146 1) How is SOC distributed among the fractions at national scale?
- 147 2) Which driving factors are relevant for this distribution?
- 148 3) Can regions of high vulnerability to carbon losses be identified by this predictive approach?

149

150 **2 Material & Methods**

151 **2.1 Study area, sampling and sample selection**

152 Germany has a total surface area of 357 000 km² and its climate is temperate, marine and
153 continental. Mean annual precipitation (MAP) ranges between 490 and 2090 mm and mean annual
154 temperature (MAT) between 5.7 and 11.2 °C. Around half the country’s surface area is used for
155 agriculture, with cropland accounting for 71% of this area, grassland for 28% and other crops (e.g.
156 vines) for 1%.

157 Soil samples were taken in the course of the ongoing German Agricultural Soil Inventory. By May
158 2017, 2900 agricultural sites (croplands and grasslands) were sampled based on an 8 km x 8 km grid.
159 At each site, a soil profile was characterised by a soil scientist and soil samples were taken from five
160 fixed depth increments, using 2-10 sampling rings per depth increment (depending on the stone
161 content) that were representatively distributed. All soils were classified in the field according to the
162 German Soil Classification System (Sponagel et al., 2005).

163 For this study, a representative set of calibration sites was needed to be able to predict the carbon
164 fractions using NIRS. Therefore, 145 calibration sites were chosen according to the following criteria:
165 1) Maximum difference in NIR spectra, according to the Kennard-Stone algorithm (Daszykowski et al.,
166 2002), 2) consistent spatial distribution within Germany, 3) exclusion of sites with SOC content > 87 g
167 kg⁻¹ in any horizon, as such soils may be organic (> 30% organic substance) or in transition between
168 organic and mineral soils and it was assumed that the processes governing the variability of SOC in
169 organic soils differ from those in mineral soils, and 4) representative mapping of land-use, soil type
170 and carbon stocks. The topsoils (0-10 cm) of these 145 sites were fractionated to provide the
171 calibration set for the prediction of the carbon fractions in the remaining sites using NIRS. After
172 obtaining the predicted carbon fractions for all 2900 sites, the machine learning algorithm cforest
173 was employed to identify driving factors important for the distribution of SOC into fractions. The
174 employed fractionation scheme is described in section 2.3 while details on the NIRS and
175 chemometrics are given in section 2.4. The use of the cforest algorithm is explained in section 2.5.

176 **2.2 Laboratory analyses**

177 All 2900 topsoil samples were dried and analysed for gravimetric water content, electrical
178 conductivity (EC), pH, SOC content (g kg⁻¹, by dry combustion), soil inorganic carbon content (g kg⁻¹)
179 after removing organic carbon in a muffle kiln, texture (by the pipette method), rock content, root
180 content and bulk density (with repeated soil rings). The SOC stocks were calculated as suggested by
181 Poeplau *et al.* (2017), taking into account the stone and root content of the soil.

182 **2.3 Fractionation of calibration samples**

183 The topsoil samples (0-10 cm depth) of the selected calibration sites were dried at 40°C to constant
184 weight and sieved to a size <2 mm. Three different fractions were prepared, using an adaptation of
185 the fractionation scheme proposed by Golchin et al. (1994):

186 1) To obtain the fraction that contains intra-aggregate particulate organic matter (iPOM), 20 g of soil
187 sample were placed in a falcon tube, which was then filled to 40 mL with sodium polytungstate (SPT)
188 solution (density=1.8 g mL⁻¹). The sample was dispersed ultrasonically at 65 J mL⁻¹ to standardize the
189 treatment of the iPOM fraction, which is often isolated by shaking in other studies. The probe energy
190 supply was calibrated using the procedure explained in Puget *et al.* (2000). The tube was centrifuged
191 at 4000 rpm until there was a clear distinction between the iPOM fraction and the remaining soil
192 pellet. The supernatant was then filtered through a 45 µm filter paper and a ceramic filter using
193 vacuum filtration. The iPOM fraction remained on the filter and was rinsed with distilled water until
194 the electrical conductivity of the filtered water was below 10 µS m⁻¹. The iPOM fraction was then
195 dried at 40°C, weighed and milled.

196 2) To obtain the particulate organic matter occluded in aggregates (oPOM) fraction, the falcon tube
197 containing the pellet was again filled to 40 mL with SPT solution. The pellet was mixed with the
198 solution using a vortex shaker and then ultrasonic dispersion was applied again, at 450 J mL⁻¹. This
199 energy level was chosen as Schmidt et al. (1999) found that 450 to 500 J mL⁻¹ is enough to disperse all
200 soil aggregates (including microaggregates) in a wide range of soil types. The sample was centrifuged
201 and the oPOM fraction was processed as described above for the iPOM fraction.

202 3) The remaining soil pellet was assumed to contain the mineral-associated organic matter (MOM or
203 heavy) fraction. The pellet was washed three times with 40 mL of distilled water, dried, weighed and
204 milled in the same way as the iPOM and oPOM fractions. The organic carbon (C) and total nitrogen
205 (N) content of the three fractions were determined through thermal oxidation by dry combustion
206 using an elemental analyser (LECO Corp.). One possible limitation of the applied fractionation scheme
207 is that pyrogenic carbon ends up in the light iPOM and oPOM fractions although it generally has

208 | ~~higher-longer~~ turnover times than assumed for this fraction. For Germany, however, we are confident
209 | that this is not influencing the results, as pyrogenic carbon only plays a minor role in German soils
210 | (Schmidt et al., 1999a). The fractionation method applied is only one out of several possible methods
211 | and options to separate labile from stabilised SOC.

212 | The carbon recovery rate of the fractionation approach was between 80 and 110%. Recovery rates of
213 | more than 100% can be reached ~~as-if~~ the sample that is measured for total SOC ~~or water content~~ -and
214 | the sample that is fractionated are not exactly the same. Even through careful subsampling the
215 | samples cannot be ~~completelycompletely~~ homogenized concerning their carbon content. The mean
216 | carbon contents of the fractions were 34.7% for the iPOM fraction, 27.4% for the oPOM fraction and
217 | 1.8% for the MOM fraction.

218 | Basic descriptive statistics were calculated for the data on the fractionated calibration sites, including
219 | mean absolute and relative proportions of the SOC fractions divided between different land-uses and
220 | soil texture classes. An ANOVA was conducted to determine whether the differences between
221 | cropland and grassland land-uses were significant and to test for significant differences between soil
222 | texture classes. The Games Howell post-hoc test was used for this purpose.

223

224 | **2.4 Near-infrared spectroscopy and chemometrics**

225 | As the oPOM fraction generally contained a small proportion of total SOC (on average 4%), it was not
226 | reliably predictable on its own. Therefore, it was combined with the iPOM fraction to give a 'light
227 | fraction' for the purpose of prediction. This was done even though it is clear that iPOM and oPOM
228 | ~~may are likely to~~ differ in their availability for decomposition and in their turnover times. In this case
229 | an accurate prediction of the combined light fraction was thought to be more important and better
230 | than an inaccurate prediction of the oPOM fraction, as this can be misleading for the readers when
231 | displayed on a map. Soil samples were dried at 40°C, sieved through a 2 mm sieve and finely milled in
232 | a rotary mill. Before analysis, the samples were dried again at 40°C and equilibrated to room
233 | temperature for a few minutes in a desiccator. The soil samples were scanned with spot size 4 cm

234 diameter in a Fourier-Transform near-infrared spectrophotometer (FT-NIRS, MPA - Bruker Optik
235 GmbH, Germany). Spectral data were measured as absorbance spectra (A) according to $A = \log(1/R)$,
236 where R is the reflectance expressed in wave number from 11000 to 3000 cm^{-1} (NIR region) with 8
237 cm^{-1} resolution and 72 scans. The final spectrum was obtained by averaging two replicates.

238 To improve the model accuracy a spectral pre-treatment was applied, using Savitzky-Golay first
239 derivative smoothing (3 points) and wavelength selection from 1330 to 3300 nm, since these regions
240 contain the main absorbance information. The calibration set consisted of the 145 calibration site
241 samples, and the remaining samples were used for prediction. Partial least squares regression (PLSR)
242 was performed in the pls package (Mevik et al., 2015), based on near-infrared (NIR) spectra and
243 reference laboratory data. A cross-validation was applied using leave-one-out to avoid over- and
244 under-fitting. To obtain the carbon fractions and ensure that the sum of light and heavy fractions was
245 equal to total SOC content, the log ratio of the light and heavy fraction was predicted (~~Jaconi et al., in~~
246 ~~review~~). A validation using an independent validation set was not deemed advisable in this study as
247 the calibration dataset was representative for the whole area of Germany including a diverse set of
248 soil types and geographical circumstances. Moreover, 145 samples are not a large dataset for a
249 calibration and with every split of this dataset a large part of the variation present in German soils
250 would be lost for the calibration. An independent validation using the same dataset was carried out,
251 however, ~~by Jaconi et al. (in review)~~ and the calibration and validation results can be found in table
252 S3. Model performance was evaluated using the root mean square error of cross-validation
253 (RMSECV), Lin's concordance correlation coefficient (ρ_c) and the coefficient of determination (R^2)
254 between predicted and measured carbon content in the fractions. In addition, the ratio of
255 performance to inter-quartile range (RPIQ) and the residual prediction deviation (RPD) were
256 calculated, the latter using the classification system devised by (Chang et al., 2001). This classification
257 is arbitrary, but nonetheless, can be used to assess the model quality and to compare with other
258 models.

Feldfunktion geändert

259 | We used the methodology as above described as ~~Jaconi et al. (in review) found that~~ NIRS is one
260 | promising method to predict carbon fractions, which is fast, low-cost and accurate. The authors had
261 | the following calibration results: For prediction of carbon content in the fractions (g kg^{-1}), the
262 | coefficient of determination (R^2) between predicted and measured carbon content in the fractions
263 | was found to be 0.87-0.90 and RMSECV was 4.37 g kg^{-1} . The RPD was 2.9 for the prediction of carbon
264 | content in the light fraction and 3.2 for the prediction in the heavy fraction. For prediction of carbon
265 | proportions in the fractions (%), R^2 was 0.83, RMSECV 11.45% and RPD 2.4 (Fig. S1; ~~for more details~~
266 | ~~see Jaconi et al., in review~~). The accuracy of prediction of both SOC content and proportions of the
267 | light and heavy SOC fractions was very good and was comparable with that in other studies that have
268 | used NIRS to predict SOC fractions (Cozzolino and Moro, 2006; Reeves et al., 2006).

269 **2.5 Drivers of soil organic carbon distribution in fractions**

270 | A total of 75 potential drivers of differences in carbon proportions in different fractions was compiled
271 | from the soil analysis data, complemented with data from a farm survey and geographical data (for a
272 | complete list of predictors, see Table S2). The farm survey recorded management practices, over the
273 | 10 years, if known by the farmer, prior to sampling. Using this, yearly mean carbon and nitrogen
274 | inputs through plant material and organic and mineral fertilizers were calculated for each site based
275 | on the yield of the main product and on different carbon allocation functions for different crops as
276 | described in (Bolinder et al., 1997) When data were missing in the survey responses, yields were
277 | calculated using regional yield estimates provided by the regional governments. Climate and site data
278 | acquired from GIS data layers completed the set of predictor variables (climate data from Deutscher
279 | Wetterdienst, normalised difference vegetation index (NDVI) data from ESA, elevation data from
280 | Bundesamt für Kartographie und Geodäsie). For the sites in the federal states of Lower-Saxony,
281 | North-Rhine Westphalia, Mecklenburg-Western Pomerania, Rhineland-Palatinate, Saxony Anhalt and
282 | Schleswig Holstein (Northern Germany), the land-use history was researched using historical maps
283 | (dating back to 1873-1909), as many regions in these states are known to have a heathland or
284 | peatland legacy.

285 The conditional inference forest algorithm (cforest; Hothorn *et al.*, 2006), was used to identify the
286 most influential drivers of SOC distribution among the different fractions. Cforest is an ensemble
287 model and uses tree models as base learners that can handle many predictor variables of different
288 types and can also deal with missing values in the dataset (Elith *et al.*, 2008). The cforest algorithm is
289 similar to the better known random forest algorithm, a non-parametric data mining algorithm that
290 uses recursive partitioning of the dataset to find the relationships between predictor and response
291 variables (Breiman, 2001).

292 Bootstrap sampling without replacement was carried out in order to prevent biased variable
293 importance (Strobl *et al.*, 2007). As multicollinearity between the predictors may result in a biased
294 variable importance measure in cforest algorithms (Nicodemus *et al.*, 2010), the correlations
295 between the predictor variables were controlled. When the correlation between two possible
296 predictors was > 0.8 , only the one with the broader range of variation was kept in the dataset. Ten
297 cforest models were created, each containing 1000 trees and using different random subset
298 generators. From these models, the variable importance of predictors was extracted and the relative
299 variable importance was calculated and averaged over all 10 models. Variables were considered
300 important when their relative variable importance was higher than $100/n$, where n is the number of
301 predictors in the model. This is the variable importance that each variable would have in a model
302 where all variables are equally important (Hobley *et al.*, 2015). It should be noted that the relative
303 variable importance value obtained from the cforest algorithm does not necessarily imply direct
304 relationships between the proportion of SOC in the light fraction and the main drivers, as the
305 algorithm also takes into account interaction effects between the variables. Model performance was
306 assessed by the coefficient of determination (R^2), as defined by the explained variance of out-of-bag
307 estimates, which represent a validation dataset:

$$R^2 = 1 - \frac{MSE_{OOB}}{Var_z} \quad (1)$$

308 where MSE_{OOB} is the mean squared error of out-of-bag estimates and Var_z is the total variance in
309 the response variable.

310 A range of soils in northern Germany, called 'black sands', behaved quite differently from other soils
311 in the country in terms of the driving factors for SOC distribution among the fractions. Therefore the
312 dataset was split into two parts for the cforest analysis and the cforest algorithm was used on: 1) the
313 dataset containing only the black sands from northern Germany (n=264). Those were extracted using
314 the NIR spectra, which were classified into black sands and non-black sand normal-soils using the
315 simca function in the "mdatools" package (Kucheryavskiy, 2017); and 2) on all other soils considered
316 not to be black sands (n=2406). All statistical analyses were conducted using the software R . Maps
317 were generated with the software QGIS.

318 **3 Results**

319 **3.1 Carbon distribution among measured fractions (145 calibration sites)**

320 | The iPOM fraction contributed an average of 23% to bulk SOC ($23\% \pm 2.36$ (mean \pm standard error
321 | (SE)) in croplands and $25\% \pm 3.8$ in grasslands (Fig. 1). The oPOM fraction accounted for an average of
322 | 4% of SOC ($3\% \pm 0.5$ in croplands, $8\% \pm 1.3$ in grasslands) across all calibration sites (Fig. 1). The heavy
323 | fraction contributed the highest proportion to bulk SOC (73% in all soils, $73\% \pm 2.5$ in croplands and
324 | $68\% \pm 4.4$ in grasslands). The differences of the distribution of C into fractions between land-uses
325 | were not significant. There was great variation in the carbon distribution between fractions, with the
326 | iPOM fraction contributing between 3 and 99% to bulk SOC. The absolute carbon content (g kg^{-1}) of
327 | the fractions was significantly different for the heavy fraction, with grasslands having significantly
328 | higher heavy fraction carbon content than croplands ($31 \text{ g kg}^{-1} \pm 3$ compared with $13 \text{ g kg}^{-1} \pm 0.7$).

329 | There were significant differences in the contribution of the different fractions to bulk SOC
330 | depending on the main soil texture class (Fig. 2). In sandy soils, the iPOM fraction contributed
331 | significantly more and the heavy fraction contributed significantly less to bulk SOC than in other soils.
332 | For the oPOM fraction, the difference between sandy soils and clayey, silty and loamy soils was not
333 | significant. The absolute SOC content (g kg^{-1} soil) was significantly higher in the heavy fraction of
334 | clayey soils than in the heavy fraction of all other soil textures and it was significantly higher in the
335 | oPOM fraction of sandy soils than in the oPOM fraction of all other soils.

336 **3.2 Influences on soil organic carbon distribution among fractions (all 2900 sites)**

337 | With the machine-learning algorithm cforest, 75 variables that may act as drivers for the regional
338 | distribution of SOC fractions were evaluated (Fig. 3a). For the 'normal' non-black sand soils (non-black
339 | sands) dataset, soil texture had the highest explanatory power in predicting the contribution of the
340 | light fraction to bulk SOC (Fig. 4), with clay content being negatively and sand content positively
341 | correlated with percentage of SOC in the light fractions. The SOC content, bulk soil C/N ratio, land-

342 use, soil type, pH and CaCO₃ content were also identified as important explanatory variables when
343 predicting the light fraction proportion. The SOC content showed a positive relationship with light-
344 fraction SOC proportion and with bulk soil C/N ratio. The grassland soils showed a higher proportion
345 of bulk SOC in the light fraction than the cropland soils and pH was negatively related to the light-
346 fraction SOC proportion. Comparing the fractions distribution in the different soil types, it is obvious
347 that podzols store a substantially higher proportion of their total SOC in the light fraction than all
348 other soil types (Fig. 6).

349 The analysis of historical land-use data of northern Germany confirmed that the former peatland,
350 heathland and grassland sites had significantly higher ($p < 0.01$) proportions of bulk SOC in the light
351 fraction than sites used as cropland in the same period (Fig. 5a). These historical peatland, heathland
352 and forest sites also had significantly higher ($p < 0.05$) C/N ratio than the historical cropland and
353 grassland sites (Fig. 5b). Regarding the total SOC content, historical peatland and grassland sites had
354 significantly higher ($p < 0.001$) values than historical croplands (Fig. 5c).

355 For the black sands dataset, bulk soil SOC content was the most important driver of SOC distribution
356 in the fractions (Fig. 3b), followed by C/N ratio, soil temperature in summer and soil bulk density. The
357 SOC content had a positive relationship with percentage of SOC in the light fraction, and with C/N
358 ratio (Fig. 4). For soil temperature there was no clear relationship. There was a negative relationship
359 between SOC proportion in the light fraction and soil bulk density.

360 **3.3 Distribution of soil organic carbon into fractions across Germany**

361 Regions featuring high proportions of SOC in the light fraction (over 60% of total SOC) nearly all lie in
362 northern Germany (Fig. 7). Medium proportions of SOC in the light fraction (40-60% of total SOC)
363 were found in Mecklenburg-Western Pomerania and in parts of Brandenburg (north-east Germany).
364 Low proportions (< 40 %) of SOC in the light fraction were found in central and southern Germany.
365 Considering the absolute contents of SOC in the light fraction (Fig. 8), it was obvious that the
366 absolute (in g/kg) and relative (in %) carbon contents in the light fraction are in close alignment in

367 most regions in Germany, implying that those sites with a higher total SOC content also have a higher
368 proportion of this content stored in the light fraction.

369 4 Discussion

370 4.1 Contribution of soil organic carbon fractions to bulk soil organic carbon

371 The relative distribution of carbon among different fractions did not differ significantly between
372 croplands and grasslands (Fig. 2a) in the calibration dataset (n=145) which is in agreement with
373 previous findings for south-east Germany (Wiesmeier et al., 2014). There was a trend, however, for
374 slightly higher iPOM content in grasslands than in croplands. When taking the full dataset, including
375 the fractions predicted with NIRS, the difference was significant ($p < 0.05$), with higher proportions of
376 POM in grassland topsoils when compared to cropland (not shown). Other studies, however, found
377 considerably higher differences between POM proportions in grassland and cropland soils.
378 Christensen (2001) estimated that, in grassland soils, 15-40% of SOC is stored in the light fraction and
379 Poeplau and Don (2013b) found the light fraction proportion to be twice as high in grassland topsoils
380 (0-10 cm) compared to cropland soils. One possible reason for a larger light fraction in grassland soils
381 is the permanent vegetation cover and the high amount of roots, which provide a higher
382 aboveground and belowground input of SOC (Christensen, 2001). The limited difference in light
383 fraction between cropland and grassland soils shown in our study can possibly be due to interfering
384 factors, as historical land-use changes which would need deeper investigations to unravel.
385 Moreover, grasslands and croplands are generally located on different soil types which, again,
386 interferes with other factors as soil moisture or texture. Therefore, it is not always possible to draw
387 direct conclusions on land-use change effects on carbon fractions from such regional inventories.

388 The significant differences observed in the absolute SOC content of fractions between different land-
389 uses were to be expected, as grassland soils in Germany contain on average more than twice as
390 much SOC in the upper 10 cm as cropland soils ($42 \pm 16 \text{ g kg}^{-1}$ compared with $17 \pm 9 \text{ g kg}^{-1}$, Fig. 2b). This
391 higher carbon content of grassland soils is often found and can mainly be attributed to the higher
392 SOC inputs and the lack of tillage induced SOC mineralization in the topsoil (Post and Kwon, 2000;
393 Wiesmeier et al., 2014).

Formatiert: Schriftart: 11 Pt., Englisch

/ Verdichtet durch

394 All samples with medium or high proportions of SOC in the light fraction were found to originate
395 from northern Germany. This is the area in which the black sands are present, which store large parts
396 of their SOC in the light fraction. Springob & Kirchmann (2002a) examined the presence of black
397 sands in Lower Saxony in Germany and linked it to the land-use history. In Ap-horizons of soils
398 formerly used as heathland or plaggen, they found a high fraction of SOC resistant to oxidation with
399 HCl. This HCl-resistant fraction was positively correlated with the total SOC content, but soil microbial
400 biomass carbon content showed a negative relationship with total SOC and, when incubated, the
401 specific respiration rates were lowest for the soils with the highest SOC content (Springob &
402 Kirchmann, 2002a). Those authors concluded that a high proportion of the organic matter in the
403 former heathland soils is resistant to decomposition and suggested that low solubility of the SOC
404 could be responsible for its high stability. A recent study (Alcántara et al., 2016) reported similar
405 results for sandy soils under former heathland, which had lower respiration rates per unit SOC and a
406 wider range of C/N ratios than control soils without a heathland history. Certini *et al.* (2015) showed
407 that SOC under heathlands is rich in alkyl C and contains high contents of lipids, waxes, resins and
408 suberin, all of which hinder microbial degradation. This confirms the claim that sandy soils under
409 former heathland and contain high contents of stable SOC even though they also contain a high
410 amount of POM. In such soils, the POM fractions may not be directly linked to higher turnover rates
411 and lower stability.

412 “Historical” peatlands may have lost much of their former carbon stocks due to a number of reasons:
413 Drained peatlands emit huge amounts of CO₂ (German grasslands on average 27.7 to CO₂ ha⁻¹ yr⁻¹,
414 (Tiemeyer et al., 2016)) until the peat has virtually vanished. There might have also been peat
415 extraction, and the remaining peat layer might have been mixed with underlying sand. Finally, former
416 peatland soils were often mixed with large amounts of sand in order to make them usable for arable
417 cultivation, but still often contain substantial proportions of (degraded) peat and therefore have
418 relatively high SOC content, with a large part of the SOC in the light fraction. It has been found
419 elsewhere (Bambalov, 1999; Ross and Malcolm, 1988; Zaidelman and Shvarov, 2000) that the SOC

420 content in sand-mix cultures declines rapidly after mixing with sand and that the decline increases
421 with increasing intensity of mixing. In a 15-year long-term trial, Bambalov (1999) found that the SOC
422 content of a sand-mix culture could only be stabilised (at much lower SOC content than the original
423 peat) by adding organic and mineral fertilisers to the soil. In contrast, Leiber-Sauheitl et al. (2014)
424 found that a peat-sand mixture with a SOC content of 93 g kg⁻¹ emitted as much CO₂ as an adjacent
425 shallow “true” peat. Similarly, Frank *et al.* (2017) determined a higher contribution of soil-derived
426 dissolved organic carbon at a peat-sand mixture compared to the peat, which points to a low stability
427 of the SOC in this kind of soils. This means that, for the light fraction of the former peatlands in
428 northern Germany, enhanced stability of the POM cannot be assumed. Thus, for more accurate
429 interpretation of results, the black sands had to be divided into a former heathland group, containing
430 a relatively stable light fraction, and a former peatland group, containing a relatively labile light
431 fraction, although there are transitional vegetation types with heath on peatlands.

432 Land-use history clearly continues to influence soil SOC dynamics, since the light-fraction SOC
433 proportion and the bulk soil C/N ratio were higher in soils with a heathland or peatland history in the
434 present study. This supports findings by Sleutel *et al.* (2008) that the chemical composition of pairs
435 of relict heathland and cultivated former heathland soils is very similar. Unfortunately former
436 peatlands and heathlands are not necessarily distinguishable due to their SOC content and C/N ratio,
437 so that knowledge on the land-use history is necessary. In some cases, however, even the distinction
438 on site can be difficult, e.g. on dry peatlands with heath vegetation (*Calluna*, *Erica*). In future studies
439 it would therefore be interesting to incubate pairs of former heathland and peatland in order to be
440 able to make accurate claims on the vulnerability of the light fraction SOC in these soils.

441 The presence of black sands poses a problem for interpretation of the SOC fractions. In most cases,
442 the SOC in the light fraction (iPOM + oPOM fractions) is seen as representing a labile carbon pool
443 with short turnover times. Therefore sites with high proportions of bulk SOC in the light fraction
444 would be seen as being at risk of losing this substantial part of their SOC stock quite rapidly and
445 easily. For the black sands, however, their former heathland land-use history has led to quite stable

446 and not easily degradable POM (Overesch, 2007; Sleutel et al., 2008; Springob and Kirchmann, 2002),
447 while for former peatland that was drained and possibly mixed with sand the classification of the
448 light fraction into a labile SOC pool may well be justified (Leiber-Sauheitl et al., 2014). This implies
449 that the results need to be interpreted in a different way for black sands than for other soils.

450 4.2 Driving factors for carbon distribution into fractions

451 4.2.1 ~~Normal~~Non-black sand agricultural soils (~~non-black sands~~)

452 The most important driver for the SOC distribution among the fractions in non-black sand ~~'normal'~~
453 soils was the soil texture (Fig. 3a). This is well in line with the frequently reported relationship
454 between clay content and mineral-associated (heavy fraction) SOC, whereby clayey soils can stabilise
455 SOC through mechanisms that protect it against microbial decay by absorption or occlusion (v.
456 Lützow et al., 2006; Six et al., 2002). The SOC that is bound to the mineral phase is mostly assigned to
457 a conceptual stable SOC pool. The negative relationship between SOC content and percentage of SOC
458 in the heavy fraction (Fig. 4) may indicate SOC saturation of the mineral fraction at rising SOC
459 content, so that excess SOC can only be stored as particulate organic carbon.

460 The positive correlation between soil C/N ratio and C proportion in the light fraction (Fig. 4) is related
461 to the inherent higher C/N ratio of the light fraction compared with the heavy fraction. Thus, a higher
462 share of light-fraction C leads to a higher C/N ratio of the bulk soil. Thus, in ~~'normal'~~non-black sand
463 agricultural soils the C/N ratio may be useful as an indicator of SOC stability: A high C/N ratio
464 indicates a high proportion of labile SOC in the soil.

465 The fact that land-use is an important driver for the distribution of SOC among the fractions is mainly
466 due to the fact that in the dataset containing all non-black sand sites topsoils under grassland store a
467 significantly higher share of SOC in the light fraction than topsoils under cropland. This is in line with
468 higher inputs of roots, which make up part of the light fraction, into grassland topsoils. The higher
469 proportion of SOC in the light fraction was also noted in the calibration dataset (n=145), but the
470 difference was not significant in that case.

471 Apart from texture, C/N ratio and land-use, another important driving factor for the distribution of
472 SOC among fractions was the soils carbonate content. Most arable topsoils in Germany do not
473 contain carbonate. The 9% of arable soils that contained over 5% carbonate in this study consistently
474 had a high proportion of heavy-fraction carbon and were therefore classified as containing mainly
475 stabilised SOC (Fig. 4). Calcium bridges may foster absorption of SOC onto mineral surfaces and, via
476 an active soil fauna, high pH enhances the turnover and transformation of SOC from recently added
477 biomass to mineral-associated SOC that can be stabilised via absorption (Oades, 1984). In general,
478 there was a trend for a higher proportion of SOC in the light fraction with lower pH (Fig. 4), which is
479 well in line with the finding by Rousk *et al.* (2009) that SOC mineralisation is slower in soils with lower
480 pH due to a higher ratio of fungal to bacterial biomass.

481 The influence of soil type is mainly due to the Podzol soils storing a much higher proportion of bulk
482 SOC in the light fraction than all other soil type classes (Fig. 6). Podzols often develop on sandy soils
483 and therefore do not have a high capacity for SOC stabilisation in the heavy fraction (Sauer *et al.*,
484 2007).

485 **4.2.2 Black sands**

486 In the dataset containing only the black sands, soil total SOC content was the most important driver
487 for the SOC distribution among the fractions, with increasing light fraction with increasing SOC
488 content (Fig. 4). On the one hand, this could indicate saturation of the heavy fraction at high SOC
489 contents, which would lead to further storage in the light fraction only, as already mentioned above
490 for ~~normal~~ non-black sand soils. Another possible explanation is that those soils with the highest
491 SOC content in the dataset are degraded peatlands, in which a high percentage of the SOC ends up in
492 the light fraction. On former heathlands, the soil total SOC content is also quite high compared with
493 that in other sandy soils and the light fraction is mainly built up from *Calluna vulgaris* litter, since
494 *Calluna* vegetation dominates on many heathlands. *Calluna* litter contains very stable SOC due to

495 high contents of lipids, long-chain aliphatics and sterols, and may persist in the light fraction of soil
496 for decades or even centuries (Sleutel et al., 2008).

497 There is a close link between land-use history as peatland and heathland and soil C/N ratio, with high
498 C/N ratio in former heathland soils (Alcántara et al., 2016; Certini et al., 2015; Rowe et al., 2006) and
499 also often in former peatlands (Aitkenhead and Mcdowell, 2000). Therefore it is evident that land-
500 use history is a main driver for the high proportions of bulk SOC found in the light fraction in these
501 soils. This is well in line with the significantly higher C/N ratios reported for soils in Lower-Saxony and
502 Mecklenburg-Western Pomerania, which were under heathland or peatland more than 100 years ago
503 (Fig. 5). The influence of land-use history reinforces the relationship between C/N ratio and the light
504 fraction.

505 In black sands, there was a significant negative relationship between soil temperature and the light-
506 fraction SOC proportion, but this was not found for the other soils (Fig. 4). A negative relationship
507 was observed between soil bulk density and proportion of SOC in the light fraction, which was
508 evidently due to the low density of the light fraction affecting overall soil bulk density (Fig. 4).

509 Even though the land-use history was part of the dataset and we could link several of the important
510 driving factors to a history as peatland or heathland, the cforest algorithm did not identify the land-
511 use history as important driver for the SOC distribution into fractions. This was the case because we
512 did not have the detailed land-use history data for all sites. But even when running the cforest
513 algorithm only for those sites with known land-use history, it was not selected as important driver.
514 This is probably due to the fact that at the time of the land survey in 1873-1909 some of the former
515 heathland and peatland sites had already been cultivated. Therefore the land-use history would not
516 prove as a reliable indicator. We did confirm this by referring to an older land survey, dating back to
517 1764-1785. For sites that exhibited typical black sand features (e.g. high SOC proportions in light
518 fractions, high sand content, and high C/N ratio) but were not a heathland and peatland in the 19th
519 century, we often found a heathland or peatland signature on the maps from the 18th century.

520 Unfortunately this land survey from the 18th century is incomplete and we could therefore not rely
521 on it for all sites.

522 **4.3 Hot regions of labile and stable carbon in Germany**

523 | ~~land-use~~For a soil to be definitively identified as being vulnerable to SOC losses, it not only needs to
524 have a high proportion of bulk SOC in the light fraction, but also a high absolute SOC content in this
525 fraction. The map in Fig. 8 shows the absolute SOC content of the light fraction at sites of the
526 German Agricultural Soil Inventory. Comparing Fig. 7 and Fig. 8, it is evident that sites which store a
527 high proportion of their SOC in the light fraction generally also have high absolute SOC content in the
528 light fraction. This implies that those sites are really the most vulnerable to SOC losses, as they not
529 only have high proportions of SOC in the light fraction, but also the highest absolute SOC content in
530 the light fractions to lose. As the SOC in former peatland soils has been shown to be easily
531 mineralised (Bambalov, 1999), management of such sites should be aimed at stabilising the SOC
532 stocks and preventing further degradation of the peat. When there is a heathland history, it can be
533 assumed that the SOC in the light fraction is quite stable, but that does not imply that freshly added
534 litter will also be stable. In fact, it is quite likely that it will not be stable if no heathland vegetation is
535 planted. This implies that the SOC stocks on these sites will decline when the resistant litter is not
536 replenished.

537 Taking together all the important explanatory variables discussed above, regions in which the SOC
538 can be classified as mostly labile were identified. These were soils with a high proportion of light
539 fraction and without a heathland history. Such soils are mainly located in northern Germany and
540 many of those have a peatland history (Fig. 7). These soils can be seen as vulnerable to losses of a
541 high proportion of their SOC in the topsoil easily and rapidly. Loss of SOC could occur e.g. through a
542 change in management that reduces carbon inputs to the soil and therefore fails to maintain the light
543 fraction, for example a land-use change from grassland to cropland (Poeplau et al., 2011) or reduced
544 input of organic fertilisers or crop residues (Dalal et al., 2011; Srinivasarao et al., 2014). Losses of SOC

545 could also occur due to higher temperatures, which could lead to enhanced microbial activity and
546 therefore enhanced mineralisation of SOC in the light fraction (e.g. Knorr *et al.*, 2005). Former
547 peatland soils may already lose significant parts of their SOC (Leiber-Sauheitl *et al.*, 2014; Tiemeyer *et*
548 *al.*, 2016).

549 Regions with soils with a high proportion of stable SOC are located mainly in central and southern
550 Germany (Fig. 7). In these regions, soils consistently store over 60% of their SOC in the heavy
551 fraction, in which the SOC is bound mostly to the mineral surfaces of clay minerals. Thus, these soils
552 have the lowest vulnerability to losing their SOC, as losses mostly occur from the light fraction.
553 However, even in these regions up to 40% of bulk SOC is stored in the light fraction and this may be
554 lost. Therefore apparent lower vulnerability does not mean that SOC-conserving soil management is
555 not needed in these regions. It should be noted that the quality of the SOC in the light fraction is
556 probably not the same in all soils, land-use (history) and climate regions. Therefore, the vulnerability
557 and turnover time of the light fraction may also vary considerably within different regions. This can
558 be seen in the light fraction C/N ratio for example, which ranged between 11 and 43 for the 143
559 calibration sites studied here.

560 Using the combination of SOC fractionation and prediction with NIRS, it is generally possible to
561 identify regions that are more or less vulnerable to SOC losses. The results must be assessed with
562 care, however, as phenomena like non-labile light fraction in black sands can hamper the
563 interpretation. It is therefore advisable to look at different driving factors when classifying sites as
564 more vulnerable than others. Moreover, special soil phenomena are to be assessed separately from
565 non-black sand~~normal~~ soils, as the driving factors for the fractions distribution may vary
566 considerably.

567 **5 Conclusions**

568 Identification of the distribution of SOC fractions in German soils allowed clear identification of
569 regions where the SOC in agricultural soils is most vulnerable to being lost. The cforest analysis
570 provided indications of the factors driving the distribution of SOC into the different fractions. It was
571 found that soil texture, bulk soil SOC content, bulk soil C/N ratio, land-use history and pH were the
572 main drivers for this distribution in ~~normal~~non-black sand soils. In 'black sand' soils in northern
573 Germany, the SOC distribution into the fractions mainly depended on total SOC content and soil C/N
574 ratio and was directly linked to the land-use history. Former peatland or heathland still has a great
575 influence on the composition of soil SOC decades or even centuries after cultivation of the soil. In
576 some regions of Germany the majority of bulk SOC is stored in the light fraction, but this does not
577 always imply that this SOC is labile. Use of SOC fractionation techniques coupled with NIR
578 spectroscopy to extrapolate to a national soil inventory dataset was successful in predicting POM
579 fractions. However, additional knowledge on land-use history was required to determine whether this
580 POM is vulnerable to losses or not. This study focused on the topsoil only, as it has comparatively
581 high SOC stocks and is most vulnerable to changes in management. Future studies should also
582 examine the SOC distribution in the subsoil, as this would enable exploitation of all possibilities for
583 sequestering additional SOC in the soil, in order to mitigate the CO₂ content in the atmosphere.
584 Regarding soil management measures, this study provided indications on where the most prudent
585 and SOC-conserving management techniques are advisable for different regions of Germany: former
586 peatland soils in Northern Germany are most vulnerable and former heathland soils in the same
587 region are less vulnerable at the moment. The vulnerability of those heathland soils can change,
588 however, when changes in soil management occur. This study showed that through the spatial
589 upscaling of SOC fraction distribution through NIRS prediction, it is possible to elucidate the SOC
590 vulnerability and driving factors for SOC stability on a national scale.

591

594 **Acknowledgements**

595 This study was funded by the German Federal Ministry of Food and Agriculture in the framework of
596 the German Agricultural Soil Inventory. We thank the field and laboratory teams of the German
597 Agricultural Soil Inventory for their thorough and persistent work with the soil samples. Special
598 thanks go to Anita Bauer for her support with the SOC fractionation. We also want to thank Catharina
599 Riggers, Florian Schneider and Christopher Poeplau for valuable comments and discussion of a
600 former version of this manuscript. We thank Norbert Bischoff, Jochen Franz, Andreas Laggner, Lena
601 Liebert, and Johanna Schröder. Our thanks also go to the Bundesamt für Kartographie und Geodäsie
602 and the Deutscher Wetterdienst for providing geodata and climate data, respectively and to the
603 Landesamt für Geoinformation und Landesvermessung Niedersachsen and the Landesamt für innere
604 Verwaltung - Koordinierungsstelle für Geoinformationswesen for providing data on historical land-
605 use.

Figures

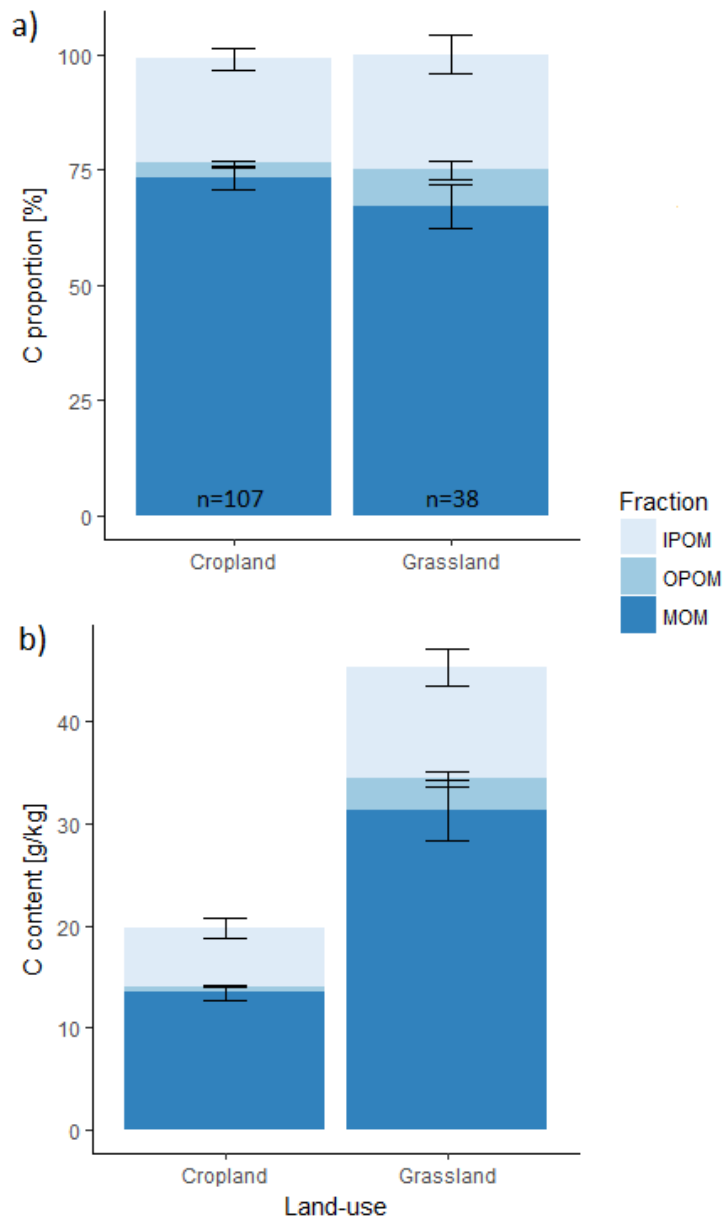

Fig. 1: a) Proportion (%) and b) absolute content (g kg^{-1}) of soil organic carbon (SOC) in the intra-aggregate particulate organic matter (iPOM), occluded particulate organic matter (oPOM) and mineral-associated organic matter (MOM) fraction in soils under cropland and grassland for the 145 calibration sites that were fractionated. Error bars denote standard error of the mean.

Fig. 2: a) Proportion (%) and b) absolute content (g kg^{-1}) of soil organic carbon (SOC) in the intra-aggregate particulate organic matter (iPOM), occluded particulate organic matter (oPOM) and mineral-associated organic matter (MOM) fraction in different soil texture classes for the 145 calibration sites that were fractionated. Error bars denote the standard error of the mean.

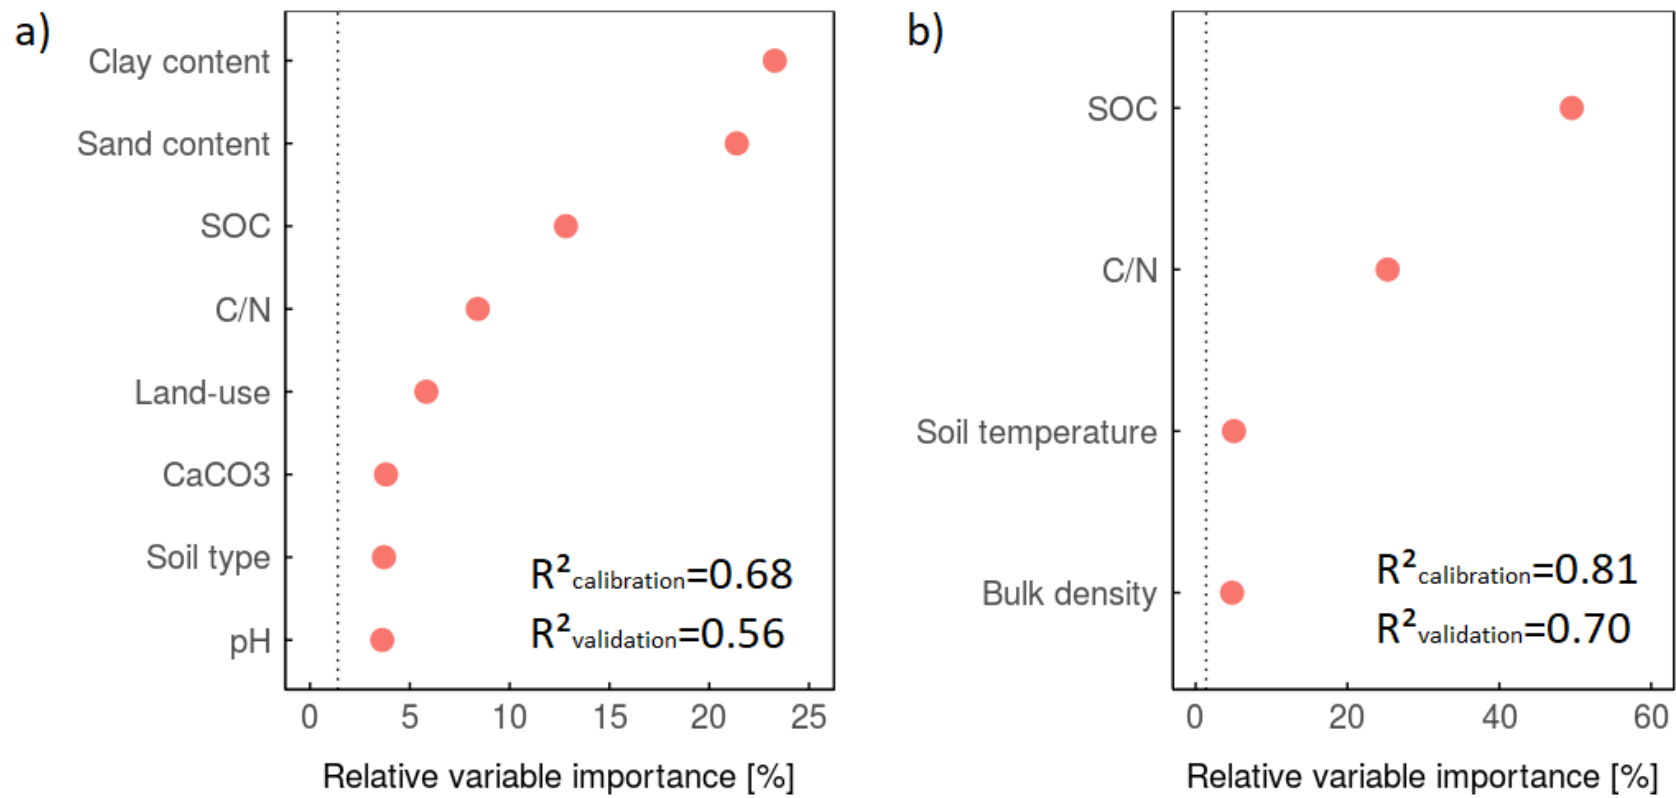

Fig. 3: Mean relative variable importance according to conditional inference forest (cforest) algorithm for predicted proportion of soil organic carbon (SOC) in the light fraction. The vertical line indicates the threshold value of relative variable importance above which a variable was regarded as important. a) Variable importance for all soils that are not black sands and b) variable importance for only black sands.

Fig. 4: Relationship between soil organic carbon (SOC) proportion in the light fraction and influential variables. Calibration sites are shown as red dots, normal non-black sand soils as black dots and black sands as orange triangles.

Fig. 5: Relationship between land-use history and a) proportion of light fraction soil organic carbon (SOC), b) carbon/nitrogen (C/N) ratio of bulk soil and c) total SOC content for all sites in the federal states of Lower-Saxony, Mecklenburg-Western Pomerania, North-Rhine Westphalia, Saxony-Anhalt, Rhineland-Palatinate and Schleswig-Holstein.

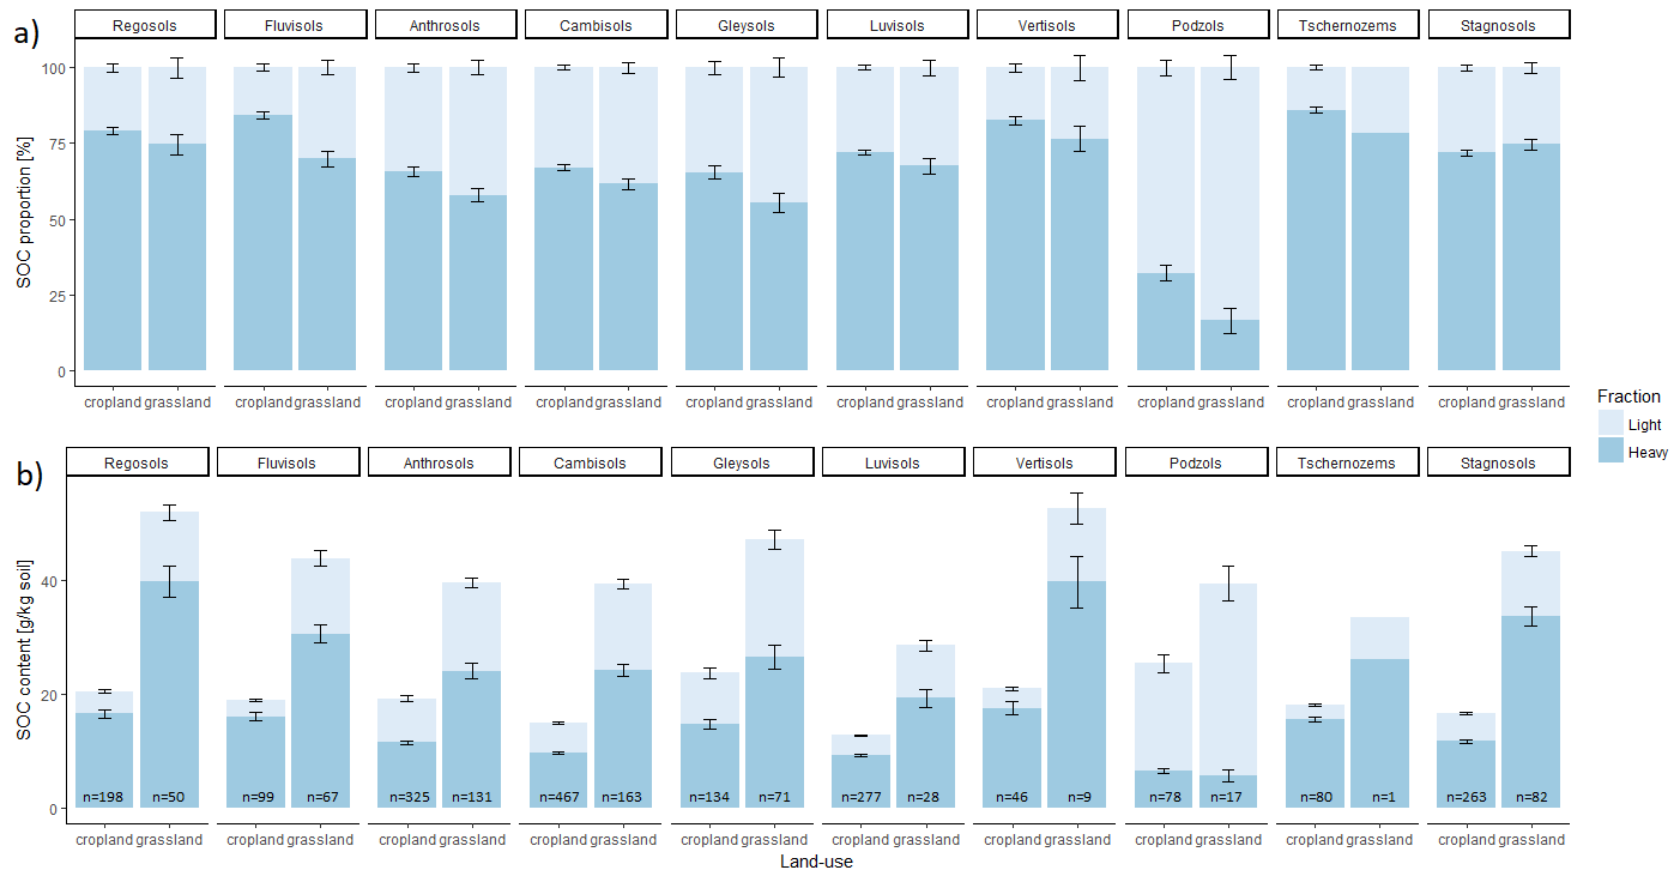

Fig. 6: a) Proportion (%) and b) absolute content (g kg^{-1}) of soil organic carbon (SOC) in the light and heavy fractions in different soil types in the non-black sand 'normal' soils (non-black sands) dataset. Error bars denote standard error of the mean.

Light Fraction SOC [%]

Fig. 7: Predicted soil organic carbon (SOC) proportion range (%) in the light fraction of soil at sites in the German Agricultural Soil Inventory.

Fig. 8: Predicted absolute soil organic carbon (SOC) content range (g kg^{-1}) in the light fraction at sites in the German Agricultural Soil Inventory.

Supplementary Material

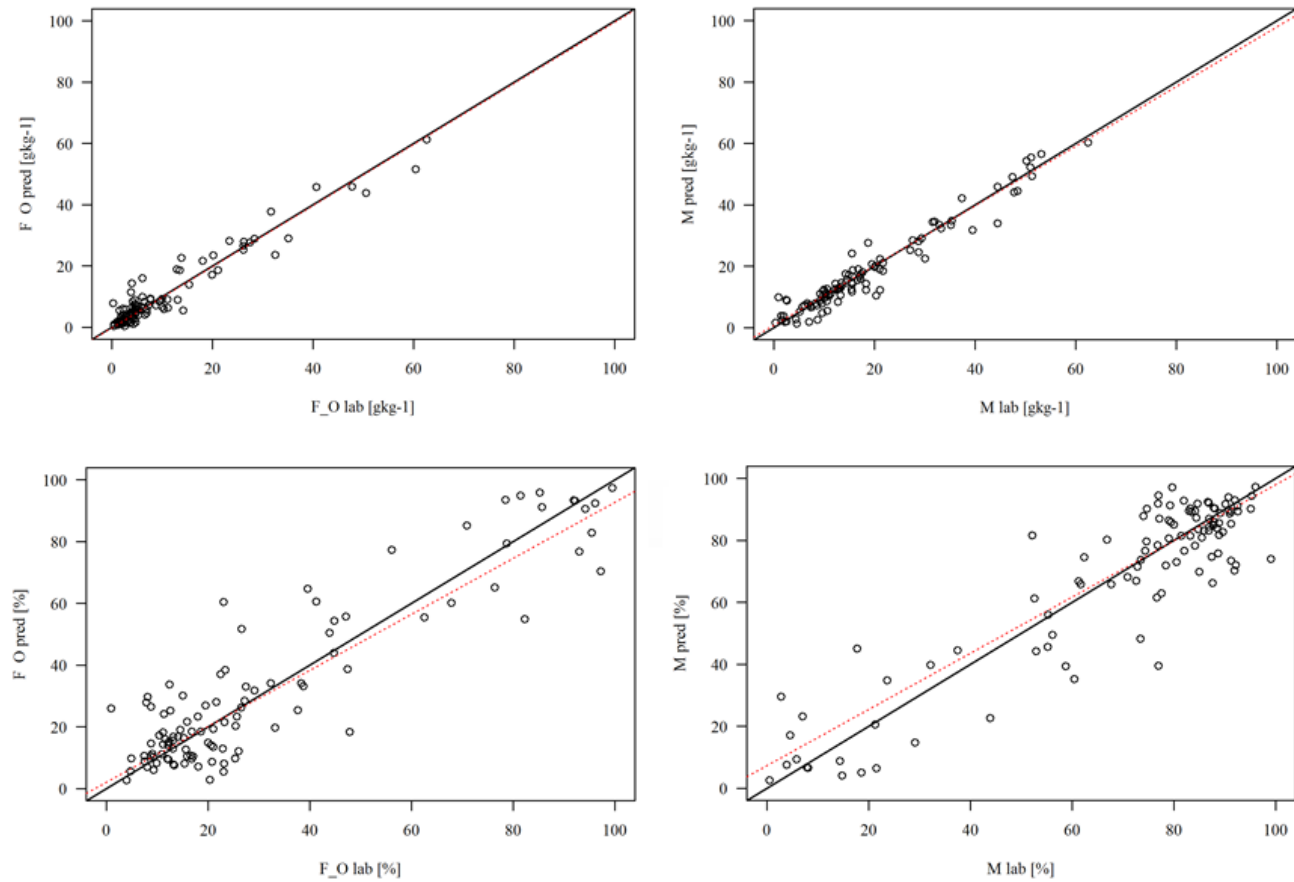

Figure S1: Measured (lab) versus predicted (pred) values for absolute content (g/kg) and proportion (%) of soil organic carbon (SOC) in fractions. M denotes the MOM fraction, whereas FO denotes the light fraction (iPOM and oPOM)

S2: Table of all predictors used for the cforest prediction

Driver	Variable type (no. of categories)	Explanation
Preuss_Nutzung1	categorical (6)	Historical land-use (1870-1900)
K1950_Nutzung1	categorical (6)	Historical land-use (1950)
K1970_Nutzung1	categorical (6)	Historical land-use (1970)
K1990_Nutzung1	categorical (6)	Historical land-use (1990)
BT_Bewirtet	integer	Length of time that the present farmer has farmed this field
BT_OekoWirt	categorical (2)	Conventional or organic farming
BP_Kalkung	categorical (2)	Does the soil receive lime?
BP_Stickstoff	categorical (2)	Does the soil receive mineral N fertiliser?
Landnutzung_aktuell	categorical (2)	Current land-use
EC_H2O	numeric	Soil electrical conductivity
pH_CaCl2	numeric	Soil pH measured in CaCl ₂
TOC	numeric	Soil SOC content
C_N_Verhaeltnis	numeric	Soil C/N ratio
CaCO3	numeric	Soil carbonate content
TRD_FB	numeric	Soil bulk density
Wassergehalt	numeric	Soil water content
Neigung	integer	Slope of sample point
Exposition	categorical (8)	Exposition of sample point
Woelbung	categorical (9)	Curvature of sample point
Microrelief	categorical (7)	Microrelief of sample point
LageImRelief	categorical (9)	Relief position of sample point
BodenAbtrag	categorical (3)	Has there been soil removal?
AnthropoVeraen	categorical (5)	Have anthropogenic disturbances taken place?
Bodenfeuchte	categorical (5)	Soil moisture at sampling
Gefuegeform1	categorical (11)	Soil aggregation1: Spatial distribution of aggregates
Gefuegeform2	categorical (13)	Soil aggregation2: Type of aggregates
Risse	categorical (8)	Width of cracks in soil horizon
RoehrenArt	categorical (5)	Type of tubes in soil horizon
RoehrenBelebt	categorical (7)	Are tubes in soil horizon occupied?
RoehrenFlaeche	categorical (7)	Surface proportion of tubes in soil horizon
Feinwurz	numeric	Mass proportion of fine roots
GrobWurz	numeric	Mass proportion of thick roots
SumSkelett	numeric	Estimated stone content in soil horizon
Substanziell1	categorical (2)	Substantial soil inhomogeneities
Strukturell1	categorical (4)	Structural soil inhomogeneities
Stratigraphie	categorical (18)	Stratigraphy
GrundwaStufe	categorical (8)	Groundwater class

GrundwaStand	numeric	Groundwater table
Moormaechtig	numeric	Peat thickness
BodentypKlasse	categorical (14)	Class of soil type
chep	numeric	C export through main crop products
cnep	numeric	C inputs through byproduct
cewr	numeric	C inputs through roots
cod	numeric	C inputs through organic fertiliser
nhep	numeric	N export through main crop products
nnep	numeric	N inputs through byproducts
newr	numeric	N inputs through roots
nod	numeric	N inputs through organic fertilisers
nmin	numeric	N inputs through mineral fertilisers
EvapotransPot	numeric	Potential evapotranspiration
EvapotransReal	numeric	Real evapotranspiration
DroughtIndexMean	numeric	Drought index
PrecYearMean	numeric	Mean annual precipitation (30 y mean)
TempYearMean	numeric	Mean annual temperature (30 y mean)
SoilMoistSummer	numeric	Soil moisture in 5 cm soil depth in summer
SoilTempSummer	numeric	Soil temperature in 5 cm depth in summer
NDVI_July	numeric	Mean NDVI in July
slope_100	numeric	Slope from digital elevation model with resolution 100m
topoidx_100	numeric	Topographical wetness index from digital elevation model with resolution 100 m
BodenAusMatKlasse	categorical (14)	Class of parent material
LN	categorical (7)	Reported land-use changes
MR	categorical (5)	Meliorative management measures
Jahre_wendend	integer	Number of years with full inversion tillage over the past 10 years
Jahrenichtwendend	integer	Number of years with reduced tillage over the past 10 years
Jahre_Getreide	integer	Number of years with grains in the rotation over the past 10 years
Jahre_FeldgrasKlee	integer	Number of years with clover in the rotation in the last 10 years
gleicheKultur5Jahre	integer	Where there five or more consecutive years with the same crop grown?
Anz_Kulturgruppen	integer	Number of different crops grown in last 10 years
Schluff	numeric	Soil silt content
Ton	numeric	Soil clay content
Sand	numeric	Soil sand content

Table S3:

Indicators of model performance for soil C fractions particulate organic carbon (POM) and mineral associated organic carbon (MOM) with calibration and independent validation dataset (mean values of 100 iterations with random selection). Table a) is for values in g C kg soil⁻¹ and table b) is for the proportion (relative values).

a)

	Q ²	Calibration dataset					Validation dataset					
		RMSECV, g C kg soil ⁻¹	ρc^*	Bias, g C kg soil ⁻¹	RPD	RPIQ	R ²	RMSEP, g C kg soil ⁻¹	ρc_r	Bias, g C kg soil ⁻¹	RPD	RPIQ
POM	0.83	4.92	0.91	0.34	2.5	1.8	0.82	5.38	0.89	0.44	2.5	2.0
MOM	0.87	4.92	0.93	-0.34	2.9	2.9	0.85	5.38	0.91	-0.44	2.7	2.6

ρc^* - Lin's concordance correlation coefficient

b)

	Q ²	Calibration dataset					Validation dataset					
		RMSECV, %	ρc^*	Bias, %	RPD	RPIQ	R ²	RMSEP, %	ρc_r	Bias, %	RPD	RPIQ
POM	0.78	13.15	0.88	1.07	2.09	2.56	0.73	15.04	0.84	1.6	1.9	2.4
MOM	0.78	13.15	0.88	-1.07	2.00	2.48	0.72	15.04	0.83	-1.6	2.0	2.3

ρc^* - Lin's concordance correlation coefficient
