25 **Abstract**

26 In this study, we combine geophysical observations from Ground Penetrating  
27 Radar (GPR) with soil physical, and geochemical properties from pedons excavated  
28 in four study areas spanning 1,300 km of the climate and ecological gradient in the  
29 Chilean Coastal Cordillera. Our aims are to: (1) relate GPR observations to depth  
30 varying soil physical and weathering-related chemical properties in adjacent  
31 pedons, and (2) evaluate the lateral extent to which these properties can be  
32 extrapolated along a hillslope using GPR observations. Physical observations  
33 considered include soil bulk density and grain size distribution whereas chemical  
34 observations are based on major and trace element analysis. Results indicate that  
35 visually-determined soil thickness and the transition from the soil B to C horizons  
36 generally correlate with maximums in the 500 and 1000 MHz GPR envelope profiles.  
37 To a lesser degree, these maximums in the GPR envelope profiles agree with  
38 maximums in weathering related indices such as the Chemical Index of Alteration  
39 (CIA) and the chemical index of mass transfer ( $\tau$ ) for Na. Finally, we find that up-  
40 scaling from the pedon to hillslope scale is possible with geophysical methods for  
41 certain pedon properties available. Taken together, these findings suggest that the  
42 GPR profiles along hillslopes can be used to infer lateral thickness variations in soil  
43 horizons, and to some degree the physical and chemical variations with depth.

46

## 47 **1 Introduction**

48 Weathering of bedrock by biotic and abiotic processes produces regolith which  
49 provides resources for life. Most biota is found in an upper mobile layer (soil), which  
50 is underlain by an immobile layer of weathered material (saprolite) that replenishes  
51 the soil with nutrients through chemical weathering and erosion that drives nutrient  
52 uplift towards the surface (e.g., Porder et al., 2007). The thickness and production  
53 of soil is influenced by topography, tectonically driven rock uplift, climate, biota,  
54 composition (mineral content), and time (e.g., Hilgard, 1914; Jenny, 1994).  
55 However, sub-surface variations in soil thickness at the scale of hillslopes are  
56 difficult to quantify because of lack of exposure. Thus, subsurface imaging by  
57 geophysical techniques, when calibrated to soil pit excavations (pedons), offers one  
58 potential mean to characterize spatial variability in soil thickness and soil properties  
59 (e.g., Mellett, 1995; Doolittle and Collins, 1995; Miller et al., 2004). Here, we  
60 evaluate the utility of applying Ground Penetrating Radar (GPR) to map variations  
61 in soil properties in diverse climate and ecological settings with stark differences in  
62 physical and chemical soil properties.

63 Previous work has attributed spatial variations in soil thickness to hillslope  
64 curvature (Heimsath et al., 1997; Heimsath et al., 1999), which determines the  
65 downslope rate of mass transport assuming a diffusion based geomorphic transport  
66 law (e.g., Roering et al., 2001). However, this single point information is spatially  
67 restricted and pedon excavations are time-intensive. To further understand spatial  
68 variations in soil and saprolite thickness, other approaches such as modeling (e.g.,  
69 Scarpone et al., 2016) and geophysical imaging (e.g., see summary in Parsekian  
70 et al., 2015) have been applied. For example, soil thickness variations were  
71 extrapolated from Digital Elevation Models (DEMs) in combination with several  
72 different observations at single locations (e.g., Scarpone et al., 2016). Different  
73 geophysical techniques have provided a non-or minimally invasive approach to view  
74 soil variations down to the saprolite and bedrock interface (e.g., Parsekian et al.,  
75 2015). Whereas high frequency GPR has proven suitable for investigating soil  
76 layering and thickness (e.g., Doolittle et al., 2007; Gerber et al., 2010; Roering et

77 al., 2010; Dal Bo et al., 2019), other methods such as seismics (e.g., Holbrook et  
78 al., 2014), Electrical Resistivity Tomography (ERT, e.g., Braun et al., 2009), and low  
79 frequency GPR (e.g., Aranha et al., 2002) are better suited to image saprolite and  
80 bedrock interfaces (e.g., Parsekian et al., 2015). GPR methods were previously also  
81 used to indirectly measure the distribution of water flow (e.g., Zhang et al., 2014;  
82 Guo et al., 2020) as well as root density (e.g., Hruska et al., 1999; Guo et al., 2013).  
83 Interpreting the interplay of GPR signals with physical and chemical soil properties  
84 within the sub-surface is challenging and not well-understood (e.g., Saarenketo,  
85 1999; Sucre et al., 2011; Tosti et al., 2013; Sarkar et al., 2019).

86 The Chilean Coastal Cordillera (Fig. 1) contains an extreme climate and  
87 vegetation gradient and it is a natural laboratory to study the influence of climate  
88 and vegetation on the sub-surface of the Earth in a setting with a similar tectonic  
89 history and lithology. The region is home to four study areas of the German-Chilean  
90 EarthShape priority program ([www.earthshape.net](http://www.earthshape.net)), where investigations of biotic  
91 interactions with critical zone processes are conducted (e.g., Bernhard et al., 2018;  
92 Oeser et al., 2018). The study areas were selected due to the arid climate in the  
93 northernmost location (26° S), and temperate rain forest conditions in the  
94 southernmost location (38° S). These four study areas are investigated to both  
95 qualitatively and quantitatively describe the differences between the four settings.  
96 Our previous work in these areas has so far identified increases in soil thickness  
97 from north to south and major and trace element compositional variations within  
98 pedons (e.g., Bernhard et al., 2018; Oeser et al., 2018; Dal Bo et al., 2019).  
99 However, a detailed comparison of geophysical, geochemical, and soil observations  
100 is yet to be conducted in these areas.

101 In this study, we investigate how physical as well as chemical observations  
102 measured at point locations (pedons) relate to GPR observations to gain further  
103 insight into the sub-surface variations. In general, we find that GPR signals can be  
104 correlated to changes in soil physical properties if these changes are of sufficient  
105 magnitude and laterally coherent. If such a correlation is observed, we discuss the  
106 links between the physical and chemical properties. The comparison of physical and

107 chemical properties with field observations and GPR data helps to better understand  
108 the sub-surface at point locations (e.g., soil thickness) and in some cases allows for  
109 up-scaling point observations to the hillslope scale along a GPR measurement  
110 profile.

111

## 112 **2 Study areas**

113 Four primary study areas are investigated in the climatic and vegetation gradient  
114 observed in the Chilean Coastal Cordillera (Fig. 1 and 2; Table 2). From N to S, the  
115 four selected areas are: a) Pan de Azúcar (~26.1° S); b) Santa Gracia (~29.8° S);  
116 c) La Campana (~33.0° S); and d) Nahuelbuta (~37.8° S).

117

### 118 **2.1 General climate, vegetation, and geologic setting**

119 The Chilean Coastal Cordillera with its climate and vegetation gradient is a  
120 natural laboratory to study the influence of climate and vegetation on denudation  
121 (Fig. 1). From N to S (~26° to 38° S), present climate ranges from arid to humid-  
122 temperate. The mean annual precipitation increases from close to zero to ~1500  
123 mm yr<sup>-1</sup>, and mean annual temperature decreases from ~20° C to ~5° C. The flora  
124 consists of small shrubs, geophytes and annual plants (Armesto et al., 1993) in the  
125 N and changes to lower-stature deciduous trees and shrubs intermix with tall  
126 evergreen mixed forest in the S. Vegetation cover increases from close to zero to  
127 ~100%.

128 Climate and vegetation in the primary study areas changed over time from the  
129 Last Glacial Maximum (LGM) to present. Mean annual precipitation during the LGM  
130 was higher than at present in all four study areas (Mutz et al., 2018). Mean annual  
131 temperature during the LGM was lower than at present except in the southernmost  
132 study area where mean annual temperature stayed the same (Mutz et al., 2018).  
133 Hence, the climate gradient observed today is comparable to the gradient during the  
134 LGM. Even though the climate was wetter and cooler during the LGM, no glaciers  
135 covered any of the study areas (Rabassa and Clapperton, 1990). Due to these

136 climatic changes over time, vegetation zones during the LGM were shifted  
137 northward by  $\sim 5^\circ$  and vegetation cover was slightly ( $\sim 5\text{-}10\%$ ) lower compared to  
138 present (Werner et al., 2018). This shift of vegetation zones to the N and the  
139 decrease in vegetation cover also likely influenced the fauna present, but to an  
140 unknown degree.

141 To compare the effect of climate and vegetation on soil thickness and GPR  
142 observations, differences in lithologies need to be minimal. However, these  
143 conditions are not always fulfilled and need to be taken into account. Whereas  
144 bedrocks in Pan de Azúcar, La Campana, and Nahuelbuta are granites to  
145 granodiorites, the bedrocks in Santa Gracia range from Granodiorites to Gabbros  
146 (Oeser et al., 2018). Hence, the parent material in Santa Gracia is lower in the  $\text{SiO}_2$ -  
147 content ( $50\text{-}65\%$ ) in comparison to the other three study areas ( $\text{SiO}_2$ -content  $>65\%$ ).  
148 Chemical weathering and physical erosion may be affected by this difference, which  
149 in turn influences soil formation and thickness.

150

## 151 2.2 Soil Characteristics

152 In each study area, depth profiles from a catena consisting of three profiles on  
153 the S-facing slope (top-slope, mid-slope, and toe-slope) and one profile on the N-  
154 facing slope (mid-slope) were described, sampled, and analyzed (Fig. 3; see also  
155 Bernhard et al., 2018; Oeser et al., 2018; Schaller et al., 2018; Dal Bo et al., 2019).

156 Previous soil studies from pedons in each area identify O, A, B, and C horizons  
157 (e.g., Bernhard et al., 2018) that overlie weathered bedrock (e.g., Oeser et al.,  
158 2018). In this study, we follow the approach of Riebe and Granger (2013) and refer  
159 to depth profiles as regolith profiles that are composed of a mobile soil layer that  
160 includes the A and B horizons, and an immobile saprolite layer represented by the  
161 C horizon.

162 In Pan de Azúcar, the soil is part of a regosol and consists of a 20 to 25 cm thick  
163 A and B horizon. The total organic carbon content is  $<0.1\%$  (Bernhard et al., 2018).  
164 The observed angular fragments in the soil increase in size ( $> 1 \text{ mm}$ ) with depth.  
165 The underlying saprolite is coarse-grained and jointed (Oeser et al., 2018). The

166 average bulk density of the soil layer is  $1.3 \text{ g cm}^{-3}$ . The cambisol in Santa Gracia  
167 consists of 30 to 55 cm thick layers of soil with A and B horizons overlying the  
168 saprolite (Bernhard et al., 2018). The total organic carbon content is 0.4%. Whereas  
169 the A horizon consists of a silt- to fine sand-sized matrix supporting up to 2 mm  
170 sized fragments, the underlying B horizon shows a transitional increase of fragments  
171 to a coarse fragment-supported fine-grained matrix (Oeser et al., 2018). The  
172 average bulk density is  $1.5 \text{ g cm}^{-3}$ . The soils and saprolites in La Campana form a  
173 cambisol. The soil layers consisting of A and B horizons are 35 to 60 cm thick and  
174 have a total organic carbon content of 1.9% (Bernhard et al., 2018). The fine sand-  
175 to silt-sized A horizon contains fragments of up to 3 mm. The matrix in the underlying  
176 B horizon is coarsening downwards and the number of fragments increases such  
177 that the horizon shifts from matrix- to clast-supported. The average bulk density is  
178  $1.3 \text{ g cm}^{-3}$ . The umbrisol in Nahuelbuta consists of a 60 to 90 cm thick soil layer (A  
179 and B horizons) and a readily disaggregating saprolite. The total organic carbon  
180 content in these soils is 6.1% (Bernhard et al., 2018). The A horizon is composed of  
181 silt-sized particles forming nodular soil aggregates. In the upper part there are up to  
182 1 mm large quartz grains embedded whereas the lower part contains large  
183 fragments. The fine sand-sized matrix of the transitional B horizon hosts subangular  
184 fragments. The amount and size of these fragments increases with depth. The  
185 average bulk density of the soil layer is  $0.8 \text{ g cm}^{-3}$ .  
186

### 187 **3 Data compilation and methods**

188 New data from 32 GPR profiles in the four study areas were collected at  
189 frequencies of 500 and 1000 MHz. These data are compared to physical and  
190 chemical properties from point locations (pedons) from previous studies (Bernhard  
191 et al., 2018; Oeser et al., 2018). These new GPR profiles complement previous GPR  
192 data collected at the same frequencies, in the same catchments (Dal Bo et al.,  
193 2019). The difference between this study and that of Dal Bo et al. (2019) lies in the

194 new, more extensive, GPR data coverage and the comparison of it to physical and  
195 chemical subsurface variations.

196 Using chemical and physical properties collected in pedons to understand the  
197 corresponding radar signatures is a difficult task requiring treatment on multiple  
198 layers. First, it would need fixed relationships translating the measured pedon  
199 properties to corresponding permittivity changes relevant for the radar signal.  
200 Second, it would need a radar forward model that successfully predicts the  
201 convolution of the emitted radar pulse with the sub-surface reflectivity. This includes  
202 among others handling constructive and destructive interference caused by closely-  
203 spaced permittivity changes in the vertical. For applications on soil, this is currently  
204 not possible because already the permittivity relationships are unclear. We  
205 therefore take a step back from the more sophisticated methods, and use simpler  
206 statistical metrics trying to isolate some properties (i.e. Pearson correlation) or  
207 combinations thereof (i.e. Principal Component Analysis) that may explain parts of  
208 the radar signatures.

209

### 210 3.1 Data compilation

211 In this study, GPR data are compared to previously published soil and saprolite  
212 physical and chemical properties (Table 1) such as: 1) soil bulk density, grain size  
213 distribution, pH, and cation exchange capacity - CEC (Bernhard et al., 2018); and  
214 2) Loss On Ignition - LOI, Chemical index of Alteration - CIA, mass transfer  
215 coefficient  $\tau$ , and volumetric strain,  $\epsilon_{\text{strain}}$  (Oeser et al., 2018). The grain size  
216 distributions provide a measure of the weight percent of different grain sizes smaller  
217 than 2 mm in the regolith, and the regolith bulk density provides a measure of how  
218 dense the soil and saprolite material is packed. The geochemical data used provide  
219 major and trace element analysis, the acid and base properties (pH) and cation  
220 exchange capacity (CEC). Major and trace element analysis allow the investigation  
221 of the loss on ignition (LOI), the chemical index of the mass transfer coefficient ( $\tau$ ),  
222 and the volumetric strain ( $\epsilon_{\text{strain}}$ ). LOI is a measure of the loss of volatile substances  
223 in a material due to excess heating (1000°C), thereby reflecting the amount of soil

224 organic matter. The degree of weathering can be quantified by the CIA which is  
225 sensitive to the removal of alkalis such as calcium, sodium, and potassium from  
226 feldspars (Nesbitt and Young, 1982). The mass transfer coefficient ( $\tau_{\text{strain}}$ ) reflects  
227 chemical gains and losses during weathering based on the elemental  
228 concentrations of mobile and immobile elements in weathered and unweathered  
229 material (e.g., Brimhall et al., 1985; Chadwick et al., 1990),  $\varepsilon$  in a regolith is based  
230 on the density  $\rho$  ( $\text{g cm}^{-3}$ ) and immobile element concentrations of the weathered  
231 regolith in comparison to the unweathered bedrock indicating volumetric gain or loss  
232 (Brimhall and Dietrich, 1987).

233

### 234 3.2 Ground Penetrating Radar (GPR)

235 Ground Penetrating Radar (GPR) is a geophysical technique based on the  
236 emission of pulsed electromagnetic waves into the subsurface and here frequencies  
237 of 500 and 1000 MHz are applied. The electromagnetic waves are reflected and  
238 scattered in the presence of dielectric contrasts at depth. The back-propagated  
239 reflected wave is then received at travel times, which depend on the depth-variable  
240 electromagnetic wave velocity  $v$ . The velocity of the media is dictated by the relative  
241 dielectric permittivity  $\varepsilon_r$  (Jol, 2009). The attenuation of the waves can be linked to  
242 the electrical conductivity  $\sigma$ . The vertical resolution depends on the system's  
243 bandwidth and the wave velocity and is in our case approximately 0.07 m for 500  
244 MHz and 0.03 m for 1000 MHz. Surface GPR can be measured in two ways  
245 including: 1) Common-Offset Profiling (COP) and 2) Common-midpoint (CMP) or  
246 wide-angle-reflection-refractions (WARR) measurements (see also Dal Bo et al.,  
247 2019). COPs measure traveltimes versus spatial position along specific transects  
248 with two antennae at fixed offsets. Here, this was done along profiles crossing the  
249 pedons (e.g., Fig. 2 and 3). WARRs are used to retrieve velocity and physical  
250 properties at the point scale with variable antennae spacing. Specifically, for each  
251 pedon a WARR was measured in a relatively flat location by keeping the transmitter  
252 position fixed at the pedon location and by moving the receiver towards the  
253 transmitter with a step size varying between 0.01 and 0.05 m depending on the

254 deployed frequency. In such way, the move-outs of linear events (air wave and  
255 ground wave) and of hyperbolic events (sub-surface reflections) could be identified  
256 using the underlying assumption that internal reflectors are not dipping.

257 Twenty-eight COP transects going from hillslope toe (near valley) to top (ridge  
258 crest) were collected in the four study areas using 500 and 1000 MHz GPR  
259 antennae (Sensor and Software Inc.). The average trace spacing of these vary  
260 between 0.01 and 0.05 m depending on frequency and location. These transects  
261 were chosen in such a way as to run between pedons, where the previously  
262 described physical and chemical properties were collected (Bernhard et al., 2018;  
263 Oeser et al., 2018). Of these 28 profiles, two were collected in the Pan de Azúcar  
264 study area, six in Santa Gracia, three in La Campana, and three in Nahuelbuta.  
265 Each profile was measured twice to total 28 (at the two frequencies). The pedon  
266 locations formed the basis for comparison to the GPR data as ground-truth data and  
267 WARRs and COPs where collected specifically at these positions (red stars, Fig. 2).  
268 Additionally, four perpendicular GPR crosslines (perpendicular to the transects)  
269 were measured at both the 500 and 1000 MHz in the La Campana and Nahuelbuta  
270 study areas. The position of each profile was determined using a differential GPS  
271 (Leica Geosystems AG) with a maximum horizontal and vertical precisions of 2 and  
272 4 cm, respectively.

273 GPR data were processed and analyzed similar to Dal Bo et al. (2019) using  
274 MATLAB. The GPR data processing procedure included: frequency band-pass filter,  
275 amplitude gain, background removal, and time-to-depth conversion (e.g., Jol, 2009).  
276 The direct air wave between receiver and transmitter was muted. Similar to Dal Bo  
277 et al. (2019), the newly measured WARR profiles at the pedon locations were  
278 processed and analyzed using a combined linear move-out – hyperbolic move-out  
279 approach. Ground wave and reflection velocities were picked, from which an  
280 average value of GPR velocity per each study area was derived and used for the  
281 time-to-depth conversion of the COP profiles (see Dal Bo et al., 2019). The  
282 averaged value of GPR velocities is used to study soil depths on hillslope scale.  
283 However, the use of an average will result in an over-/under-estimate of soil depths

284 on the hillslope scale. Signal envelopes were calculated using a Hilbert transform  
285 (Green, 2004; Liu and Marfurt, 2007). At each pedon location, a certain number of  
286 traces depending on the measurement step size (i.e. between 10 and 50) were  
287 sampled for 0.5 m uphill and 0.5 m downhill the pedon and laterally averaged for  
288 comparison to the pedon physical and chemical properties. The averaging assumes  
289 that both chemical and GPR signatures do not change with depth across that  
290 interval, an assumption that may not hold everywhere. As the GPR envelope is  
291 directly related to the electric impedance (Telford et al., 1990; Jol, 2009), the  
292 envelope onset and energy intervals could be compared to variations in physical,  
293 and potentially chemical, soil properties.

294

### 295 3.3 Statistical Correlation and Principal Component Analysis

296 Comparison between the chemical and physical pedon information (Bernhard et  
297 al., 2018; Oeser et al., 2018) and GPR data was conducted two different ways. First,  
298 we carried out a correlation analysis using the Pearson' correlation coefficient ( $r$ ).  
299 More specifically, we used the bulk density, clay content, LOI, CIA, Tau ( $\tau$ ),  
300 volumetric strain ( $\epsilon_{\text{strain}}$ ), pH, and CEC for comparison to the GPR 500 and 1000  
301 MHz antennae envelope data. The GPR envelopes were resampled and averaged,  
302 such that the depth intervals were the same as for the derivatives of the soil data (see  
303 Table S2). Furthermore, because the envelope of GPR data is sensitive to changes  
304 along the vertical direction, we also calculated the vertical gradient of the ground  
305 truth information at each sampled depth using a centered difference approximation.  
306 Following this, the R package function `corrplot` (Wei, 2012) was used to calculate  
307 the Pearson's correlation coefficient to identify correlations between the variables  
308 (Sedgwick, 2012). This analysis was done considering the entire climate and  
309 vegetation gradient and within each location. Both the original data and the  
310 derivatives were used to explore which of the two approaches delivered meaningful  
311 insights.

312 Second, we conducted a multivariate analysis of the data using a principal  
313 component analysis (PCA; Wold et al., 1987). This was done for both the entire

314 climate gradient and within each study area using the factoextra R package  
315 (Kassambara, 2017). After each PCA analysis, a scree plot was evaluated to  
316 investigate how much variance was included in each principal component (PC, Bro  
317 and Smilde, 2014). In this study, at least 70% of the variance was among the first  
318 two PCs, which were then further analyzed. The contribution of each variable to the  
319 first and second PC was computed using the eigenvalues and eigenvectors from  
320 the covariance matrix (Abdi and Williams, 2010). This resulted in a plot where the  
321 x-axis is PC1 and the y-axis is PC2 and each variable is displayed as a vector with  
322 a specific direction and length that indicate the magnitude and direction of the  
323 contribution to each PC.

324

#### 325 **4 Results**

326 Physical and chemical properties from pedons are shown with the 500 and 1000  
327 MHz GPR profiles and their envelopes with depth as well as investigated  
328 correlations and PCAs for the four study areas (Fig. 4 to 11 and supplement Figs  
329 S1 to S12; and supplement Tables S1A to D, S2A to D, S3, and S4A to E). For  
330 brevity, only the comparisons between pedon observations and GPR data are  
331 presented for the S-facing mid-slope positions in the main text (Fig. 4, 6, 8, and 10)  
332 and the remaining locations are provided in the supplementary material. Note that  
333 the envelopes are averaged over the COP data, collected over a lateral distance of  
334 1 m in total, and are therefore not point information. Given that the soil thickness  
335 increases towards the southern study areas, the 1000 MHz GPR antennae is  
336 interpreted for the (northern two) Pan de Azúcar and Santa Gracia study areas,  
337 whereas in La Campana and Nahuelbuta the 500 MHz GPR signal was used  
338 because it has a deeper penetration depth. However, we show results below for  
339 both frequency antennas to demonstrate the difference in penetration depth and  
340 resolution between the two antennae. Details for each study area (from N to S)  
341 follow.

342

343 4.1 Pan de Azúcar (northern most study area)

344 In Pan de Azúcar (Fig.1, 2A), a gradual transition from the B to the C horizon was  
345 visually observed in the pedons at 20 to 40 cm whereas the mobile/immobile  
346 boundary is considered to be at 20 to 25 cm (shaded gray areas and black line, Fig.  
347 4, Fig. S1 to S3). The available physical properties for this location do not indicate  
348 a strong change in material properties with depth. LOI and CIA indicate a minor  
349 change in properties at ~20 cm depth. A maximum in the energy envelope in the  
350 1000 MHz frequency is present at about 20 to 30 cm that could be related to the  
351 transition of material properties between the B and C horizons and the location of  
352 mobile/immobile boundary observed in the field.

353 Due to the sparse depth information for bulk density and clay content, the  
354 statistical analyses for this location was not very insightful. Whereas clay content  
355 shows a medium correlation (0.54) with the 1000 MHz GPR envelope, no strong  
356 correlation between LOI, CIA,  $\tau$ , and the 1000 MHz GPR envelope could be found  
357 (Table S3). In the PCA, three primary components (PC) explain over 80% of the  
358 variance (Table S4A). PC1 has the bigger contribution from CIA, clay content, and  
359 the 500 MHz envelope whereas PC2 has the bigger contribution from LOI, the  
360 1000MHz envelope, and  $\tau$  of Na and Zr (Fig. 5).

361

362 4.2 Santa Gracia

363 In Santa Gracia (Fig. 1, 2B), a gradual transition from the B to the C horizon was  
364 observed in the field between 20 to 60 cm depth (shaded gray region Fig. 6, Fig. S4  
365 to S6). The boundaries between the mobile/immobile layers in the pedon were  
366 observed between 30 to 55 cm depth. Bulk density and volumetric strain show slight  
367 changes around 15 and 30 cm depth. Whereas LOI and CIA do not show any  
368 changes with depth,  $\tau$  shows changes between 30 and 50 cm depth. The 500 and  
369 1000 MHz GPR profiles and envelopes show increased irregular and strong  
370 reflections at ~25 cm (1000 MHz) and 45 cm (500 MHz) depth, and also maximums  
371 in the envelope at ~25 cm (1000 MHz) and 45 cm (500 MHz) depths. These

372 variations in the reflections and maximums in the envelopes coincide with either the  
373 top or central position of the transition from the B to the C horizon.

374 A weak to moderate correlation ( $\sim 0.3$ ) between clay content as well as CIA and  
375 the 1000 MHz GPR envelope is present (Table S3). Results from a PCA analysis of  
376 the Santa Gracia data indicate that 3 components explain over 80% of the observed  
377 variance (Table S4B). PC1 explains over 35% of the variance, and includes bulk  
378 density, CIA, and the 500 and 1000 MHz envelopes (Fig. 7). PC2, explaining 31%  
379 of the variance, includes clay content, LOI, and  $\tau$  of Na and Zr.

380

#### 381 4.3 La Campana

382 Field observations from the La Campana area (Fig. 1, 2C) document a layer of  
383 cobbles (5 to 10 cm diameter) between the A and B horizon at a depth of  $\sim 30$  cm  
384 (Bernhard et al., 2018). The transition between the B to C horizons does not contain  
385 rock fragments. The transition from the B to C horizon (shaded gray area, Fig. 8)  
386 and the mobile/immobile boundary (black line, Fig. 8) are observed at 34 to 110 cm  
387 and 35 to 60 cm, respectively (see also Fig. S7 to S9). The mobile soil layer extends  
388 deeper in La Campana than in Pan de Azúcar or Santa Gracia and physical  
389 properties were available for greater depths. Bulk density and grain size change  
390 gradually with depth and no soil thickness could be determined. Also, LOI, CIA, and  
391  $\tau$  do not show an abrupt change in regolith properties. Reflection hyperbolas and  
392 irregular reflection horizons appear in the 500 and 1000 MHz GPR data at about 40  
393 to 60 cm depth above the B to C horizon transition. The second peaks of the 500  
394 and 1000 MHz GPR envelopes coincide with the B to C horizon transition.

395 In contrast to the previous study areas, the 500 MHz GPR envelope correlates  
396 moderately with CIA (0.56), pH (-0.57), and CEC (-0.39, Table S3). Three  
397 components from the PCA analysis explain about 80% of the total variance (Table  
398 S4C). PC1 ( $\sim 35\%$  of the total variance) includes LOI,  $\tau$ , and CEC, whereas PC2  
399 (31%) contains CIA, volumetric strain, and the envelopes (Fig. 9). PC3 is dominated  
400 by pH as well as  $\tau$  of Zr. In general, whereas the first energy interval (1000 MHz)

401 could be attributed to the stone layer between the A and B horizon, the second  
402 energy interval occurs close to (<10 cm) with the mobile/immobile boundary (Fig.  
403 8).

404

#### 405 4.4 Nahuelbuta (southernmost study area)

406 In Nahuelbuta, the B horizon contains pebbles and cobbles at around 60 to 80  
407 cm depth (Bernhard et al., 2018). The B to C horizon transition appears at 50 to 100  
408 cm depth (shaded gray region, Fig. 10; see also Fig. S10 to S12). The  
409 mobile/immobile boundary was identified at 60 to 90 cm depth. Density  
410 measurements in the pedon indicate a transition in bulk density between about 30  
411 to 60 cm depth where also the grain size distribution changes. The LOI and  $\tau$   
412 generally show large changes with depth, in contrast to the CIA and volumetric strain  
413 which are more homogenous with depth. The 500 MHz GPR profile indicate the  
414 existence of point targets/objects appearing as reflection hyperbola or undulating  
415 features at depths greater than 60cm. This depth is approximately the same depth  
416 at which the mobile/immobile boundary was identified, as well as changes in the  
417 physical (e.g. bulk density, percent sand) and chemical (LOI,  $\tau$ ) properties. The  
418 hyperbolas do not add up coherently during the lateral averaging and therefore do  
419 not produce a significant energy interval in the average envelope. The envelope is  
420 dominated by the energy intervals given by two reflections at about 30 to 50 cm  
421 depth. The lower set of these energy intervals could be linked with the upper  
422 physical soil boundary.

423 Results from the correlation analysis indicate the 500 MHz GPR envelope is  
424 strongly positively correlated with bulk density (0.74), strongly inversely correlated  
425 with LOI (-0.6), and moderately inversely or positively correlated with clay content (-  
426 0.37), pH (0.46), and CEC (-0.53) (Table S3). Results from the PCA analysis show  
427 that two PC components explain ~75% of the variance. PC1 (~57 %) includes bulk  
428 density, clay content, LOI, and CEC, whereas PC2 (~18 %) contains  $\tau$  of Zr and pH  
429 (Fig. 11; Table S4D). In general, as the 500 MHz GPR envelope signal correlates

430 well with bulk density and clay content, the envelope signal reflects changes in soil  
431 properties.

432

### 433 **5 Discussion**

434 Here we evaluate the chemical, physical, and geophysical observations from the  
435 pedons. Using this information, we attempt to up-scale information from the pedons  
436 to the hillslopes scale along the GPR transects. Potential soil thickness over  
437 hillslopes is discussed in light of hillslope, aspect, and the climate and vegetation  
438 gradient from N to S.

439

#### 440 **5.1 Synthesis of GPR data with physical and chemical properties from point** 441 **locations**

442 GPR data image changes in material properties that could be caused by  
443 changes in physical (e.g., bulk density, grain size variation, water content), or  
444 potentially chemical properties (e.g., pH, CEC, CIA). The interplay between these  
445 different properties can have a complicated influence on the GPR signal and  
446 therefore difficult to disentangle. Disentangling any relationship between GPR data  
447 and physical and chemical properties is further complicated as not all properties  
448 influencing GPR data are measured (e.g., water content; Jol, 2009). In addition, the  
449 determination of soil thickness (i.e., the boundary between the mobile/immobile  
450 layers) in the field causes its own problems as observed changes are transitional  
451 over a depth interval of 5 to 10 cm and not discrete. In the following, we start by  
452 discussing if GPR data can be used to image soil thickness as well as physical and  
453 chemical properties at the pedon locations where *in-situ* observations were made in  
454 each study area.

455 In Pan de Azúcar (Fig. 4, 5 and Fig. S1 to S3), the locations where GPR data  
456 can be compared to pedons shows low variability in the observed soil thickness (~20  
457 to 30 cm) at each pedon location. Whereas the 500 MHz signal shows deep (sub-  
458 soil depth) interfaces, the maximum in the 1000 MHz energy interval signal agrees

459 with the soil thicknesses observed in the field (Fig. 4 and Fig. S1 to S3). However,  
460 the boundary between soil and saprolite layers is here probably too shallow to be  
461 detected with the 1000 MHz antennae. An even higher frequency would be  
462 favourable to detect the soil/saprolite boundary. Hence the Pearson correlations and  
463 PCA results from Pan de Azúcar are restricted not only because of GPR analysis  
464 but also due to restricted physical properties. The chemical and physical properties  
465 correlate only weakly to moderately with the 1000 MHz envelopes (Table S3). The  
466 PCA results indicate that soil bulk density is not likely correlated with either the 1000  
467 MHz signal or LOI. In Pan de Azúcar, LOI does not represent soil organic matter as  
468 soils of the arid zones have low or no organic matter content. The volatile loss  
469 measured in the LOI is more likely associated with the combustion of carbonates.  
470 In general, shallow soils in the arid zone do not show much variability in soil  
471 thickness nor provide insight into the influence of physical or chemical properties on  
472 GPR signals.

473 In Santa Gracia (Fig. 6, 7 and Fig. S4 to S6), the field-observed soil thicknesses  
474 of the different pedons are more variable than in Pan de Azúcar. Although the 500  
475 MHz and 1000 MHz GPR envelopes indicate changes at depth, the physical and  
476 chemical properties observed with depth show only a few distinct changes implying  
477 that the soil thickness cannot easily be determined using only physical or chemical  
478 properties. The PCA indicates that most of the variance in PC1 is explained by the  
479 envelope signals, bulk density, and CIA whereas PC2 is dominated by clay content  
480 and  $\tau$  of Na and Zr. The clay content does not seem to be a dominant factor for the  
481 envelope signal, but rather represents a complex interaction between physical and  
482 chemical property changes that cannot be disentangled with available data. It  
483 appears that the second energy interval in the 1000 MHz envelope may agree with  
484 the observed soil thickness in Santa Gracia, and (in contrast to the Pan de Azúcar  
485 location) the first maximum in the 500 MHz envelope does agree with the observed  
486 soil thickness. These observations again underscore that for different locations with  
487 variable soil type, vegetation, and physical and chemical properties local calibration  
488 between pedons and GPR data are required.

489 The determination of soil thickness from GPR data in La Campana is as difficult  
490 as in the previous settings (Fig. 8, 9 and Fig. S7 to S9). The field observations  
491 indicate relatively large transition zones for the B to the C horizon, and some  
492 physical properties vary only weakly with depth. As a result, the determination of  
493 soil thickness with physical and chemical properties is difficult, despite the moderate  
494 to strong correlation of 500 MHz GPR envelopes with derivatives of physical and  
495 chemical properties. Whereas the variance in PC1 is explained by bulk density, LOI,  
496  $\tau$  of Na and Zr, and volumetric strain, the variance in PC2 is dominated by the  
497 envelopes, CIA, pH, and CEC. Chemical properties seem to have a considerable  
498 influence on GPR signals in this setting. In La Campana, the first energy interval of  
499 the 500 MHz envelope is interpreted to reflect the previously described stone layer  
500 whereas the second energy interval seems to match the observed soil thickness.  
501 Given these uncertainties in local conditions, a clear identification of soil thickness  
502 from GPR data is difficult, even with local calibration to a pedon.

503 Finally, in Nahuelbuta (Fig. 10, 11 and Fig. S10 to S12), the observed soil  
504 thickness in the field is the deepest of all the four study areas and reaches from 50  
505 to 100 cm. The soil thickness is easily identifiable based on physical properties. The  
506 derivatives of the physical properties correlate moderately with the available 500  
507 MHz envelope (Table 3). Furthermore, the chemical properties correlate weakly with  
508 the GPR envelopes. The variance is strongly explained by PC1 containing physical  
509 properties (e.g., bulk density, clay content, LOI) and less by PC2 including chemical  
510 properties (e.g., pH,  $\tau$  of Na and Zr). Even so changes in properties are more  
511 pronounced in Nahuelbuta than in the drier locations, a clear correlation between  
512 maximums in the 500 MHz energy envelope and soil thickness is not present. The  
513 second energy interval of the 500 MHz envelope best agrees with the observed soil  
514 thickness. However, due to local inhomogeneities caused by intense vegetation,  
515 every pedon and its attributed GPR envelope look different.

516 In summary, the 500 and 1000 MHz envelopes at point locations have the  
517 potential to be used to determine soil thickness. But, the clarity with which this can  
518 be done is variable and requires calibration to local pedons. Even with local

519 calibration, the relationships are not always clear (e.g., Fig. 8). Physical and  
520 chemical properties with depth exert a complex interplay on measured GPR signals.  
521 If a certain combination of physical and chemical properties is dominant in one  
522 setting, another combination may influence the measured GPR signal. Therefore,  
523 what GPR frequency works best for the individual study area due to different  
524 physical and chemical properties needs to be investigated with information from  
525 point locations/pedons. For the arid Pan de Azúcar and semi-arid Santa Gracia we  
526 suggest using the 1000 MHz frequency (or higher), whereas for the Mediterranean  
527 climate setting of La Campana and temperate Nahuelbuta the 500 MHz frequency  
528 proved better. Improvements in our approach to determine soil thickness from GPR  
529 data might be possible by applying multifrequency GPR techniques, which are freed  
530 from antenna effects by fusion of different frequency measurements (e.g., De Coster  
531 and Lambot, 2018). Nevertheless, the point information of soil thickness has the  
532 potential to be up-scaled to hillslopes in some settings using GPR transects after  
533 local calibration is conducted.

534

## 535 **5.2 Up-scaling to hillslopes**

536 Here we use insights gained from comparisons between GPR and point  
537 locations to extrapolate the soil thickness along the hillslope GPR profiles (Fig. 2,  
538 3). The up-scaling is carried out using a combination of amplitude and envelope  
539 depth-converted profiles. To do this up-scaling, we calculated the envelope along  
540 each profile. Then, using the known soil depth data from all pedons in one study  
541 area, this interface was estimated along the profiles by searching for the  
542 corresponding signal in the envelope at every meter. Even though the information  
543 of three-point locations is at the lower limit, the combination of field observations  
544 with GPR transects allows estimation of the lateral variability of soil thickness over  
545 hillslopes. However, given the complications mentioned in section 5.1 (e.g., which  
546 frequency GPR antenna and envelope interval to use) the up-scaling and the  
547 indicated soil thickness need to be treated with care.

548 In Pan de Azúcar (Fig. 12; Supplementary Fig. S14) the observed B to C horizon  
549 transition at point locations is typically between ~14 to 50 cm. No clear soil thickness  
550 could be determined based on GPR profiles. Nevertheless, soil thicknesses  
551 identified from 1000 MHz GPR envelopes seem to be relatively homogeneous over  
552 the entire S-facing transect with an average value of  $25 \pm 3$  cm (Table 2). In contrast,  
553 the N-facing transect indicates a thinner soil uphill than downhill where it reaches a  
554 maximum depth of ~50 cm (Fig. S14).

555 In Santa Gracia (Fig. 13; Supplementary Fig. S15 to 17), the soil thicknesses  
556 from point locations/pedons in the S-facing transect increases downslope and  
557 ranges between 20 to 60 cm (Table 2). The soil thickness based on the 1000 MHz  
558 GPR envelope at the top-slope position (SGPED20) decreases first downhill and  
559 then increases again, thereby demonstrating laterally variability along the hillslope.  
560 The soil thickness in the mid-slope position (SGPED40) is variable and reaches  
561 from 25 to 50 cm. At the toe-slope position (SGPED60) a mostly constant thickness  
562 of 30 cm is identified. In the N-facing transect almost no variability in soil thickness  
563 (~25 cm) is observed. Even so the soil thickness based on GPR envelopes cannot  
564 be used to decipher the exact soil thickness, the method still offers a close  
565 approximation of soil thicknesses determined by field observations and GPR  
566 profiles.

567 In La Campana (Fig. 14; Supplementary Fig. S18 to 20) the soil thickness from  
568 the 500 MHz GPR envelope is 35 to 70 cm. Whereas the top- and mid-slope  
569 positions in the S-facing hillslope (LCPED10 and LCPED20, respectively) show  
570 variable soil thickness between 50 and 70 cm, the toe-slope position (LCPED30)  
571 contains soil thicknesses between 35 and 70 cm. Relatively constant soil thickness  
572 of 50 to 60 cm are identified for the N-facing mid-slope position (LCPED40). Field  
573 observations do not always agree with soil thicknesses based on GPR envelopes.  
574 In the La Campana location, soil thicknesses based on GPR envelopes need to be  
575 considered with caution, but contain valuable information such as the existence of  
576 pebble layers. However, GPR profiles show hyperbolas and continuous reflections,  
577 which can be interpreted along almost all the covered length. These interfaces can

578 be reliably used to infer soil thicknesses, when a previous calibration with soil  
579 pedons has been done.

580 In Nahuelbuta (Fig. 15; Supplementary Fig. S21 to 23), soil thickness in the S-  
581 facing top-slope position (NAPED10) increase downhill from 60 to 110 cm. At the  
582 mid-slope position (NAPED20), the soil thickness is highly variable and ranges from  
583 50 to 110 cm. Soil thickness at the toe-slope position (NAPED30) is 80 to 110 cm.  
584 In the N-facing mid-slope position the soil thickness ranges from 60 to 110 cm. Soil  
585 thicknesses based on GPR envelopes are generally thicker than soil thicknesses  
586 observed in the field and do also not agree well with thicknesses based on GPR  
587 profiles. The application of GPR envelopes to determine soil thicknesses needs to  
588 be treated with care in this setting. On the contrary, GPR profiles display rather  
589 continuous reflections that might represent interfaces within the soil, and could  
590 therefore be used to extrapolate point-scale ground-truth information over the profile  
591 scale.

592

### 593 **5.3 Changes of soil thickness with hillslope position, aspect, and latitude**

594 The soil thickness imaged with GPR envelopes over hillslope transects reflect  
595 mainly physical properties, but also chemical properties (e.g., CIA,  $\tau$ ). This approach  
596 gives the opportunity to study non-invasively possible changes in soil thickness over  
597 hillslope position, aspect, and latitude (Fig. 12 to 15; Fig. S14 to S24; Table 2). Here  
598 we summarize any regional trends in soil thickness between the four study areas  
599 and different aspect (N- vs. S-facing) hillslopes (Fig. 2).

600 Soil thickness in a catena that develop under comparable climate and on similar  
601 lithologies are expected to increase downhill (e.g., Birkeland, 1999). From the top-  
602 to toe-slope position along a catena the potential for physical erosion decreases  
603 downslope due to decreasing physical potential whereas the potential for deposition  
604 increases. In Pan de Azúcar, the soil thickness based on the GPR envelopes in the  
605 S-facing hillslope are constant, whereas the N-facing hillslope indicates soil  
606 thickness increasing from top- to toe-slope. The possible slight increase in soil  
607 thickness from top- to toe-slope can be explained by low denudation rates due to

608 very low precipitation rates in Pan de Azúcar. In Santa Gracia, the constantly thin  
609 soils at the S-facing top-slope are in contrast to the thicker and more variable soil  
610 thickness in the mid-slope position. Bernhard et al., (2018) describe an increase of  
611 the A to BC horizon from top- to toe-slope in the S-facing hillslope. In Santa Gracia,  
612 precipitation and minor vegetation cover may cause the increase of the soil  
613 thickness downslope as well as the variable soil thickness in the mid-slope position.  
614 In La Campana, the soil thickness based on GPR envelopes is highly variable.  
615 Bernhard et al., (2018) observed the thickest soil also in the mid-slope position,  
616 describe a disturbed hillslope with recent erosion events (e.g., possibly due to a past  
617 fire and temporary mobilization of sediment). Therefore, the S-facing hillslope in La  
618 Campana is a disturbed system and therefore difficult to laterally extrapolate  
619 horizons. Due to the differences in soil thickness information from the different  
620 methods, soil thickness changes in hillslopes from Nahuelbuta are not further  
621 considered.

622 In the southern hemisphere the N-facing hillslope is expected to be slightly  
623 warmer (higher solar irradiation) and drier (due to higher evaporation) than the S-  
624 facing hillslope (e.g., Anderson et al., 2013). These differences in available soil  
625 moisture could potentially lead to different vegetation and soil thickness. In Pan de  
626 Azúcar, the soil thickness of the S- and N-facing mid-slope positions cannot be  
627 attributed to differences in vegetation cover because it is absent from both the N-  
628 and S-facing slopes. In Santa Gracia, however, the thicker soil in the S-facing mid-  
629 slope position than in N-facing position can either be attributed to higher vegetation  
630 cover in the S-facing position (e.g., Riebe et al., 2017) or subtle lithological changes  
631 (e.g. Oeser et al., 2018). Different vegetation on S-facing and N-facing slope  
632 positions in La Campana could explain the higher variability in soil thickness in the  
633 S-facing mid-slope positions (35 to 70 cm) than the N-facing hillslope (50 to 60 cm).  
634 However, the aspect-related differences in La Campana may represent local  
635 heterogeneities (e.g., physical erosion) rather than a hillslope aspect-related trend  
636 (Bernhard et al., 2018). Finally, in Nahuelbuta, the GPR envelopes indicate highly  
637 variable, but also slightly thicker soil thickness in the S-facing than the N-facing

638 hillslopes. A higher clay content in the S-facing than the N-facing hillslope is  
639 attributed to a more intense soil formation in the S-facing hillslope (Bernhard et al.,  
640 2018). Differences in soil thickness on S- and N-facing hillslopes are increasing from  
641 N to S in latitude due to the increasing difference of solar irradiation on evaporation,  
642 vegetation, and possible frost cracking (e.g., Riebe et al., 2017).

643 Not only is there a change in soil thickness due to aspect, but also due to the  
644 latitude. Soil thickness increases and is more variable from N to S in latitude due to  
645 different climate and biota in each study area. Increasing precipitation rates from N  
646 to S allow an increase and diversity in vegetation. From N to S in latitude, soils  
647 increase in thickness and are more variable in thickness due to the influence of biota  
648 (e.g., trees, burrowing animals). The increase in biota not only causes variable soil  
649 thickness, but also homogenizes soils by bioturbation (e.g., Schaller et al., 2018). In  
650 addition, the increase in vegetation under increasing precipitation rates causes  
651 stabilization of hillslopes due to increasing precipitation rates (e.g., Langbein and  
652 Schumm, 1958; Starke et al., 2020). Hillslope denudation rates derived from *in situ*-  
653 produced cosmogenic nuclides increase from Pan de Azúcar to La Campana and  
654 slightly decrease for Nahuelbuta (Schaller et al., 2018; Oeser et al., 2018).  
655 Increasing soil thickness generally diminishes soil production rates (e.g., Heimsath  
656 et al., 1997) which under steady-state conditions equal hillslope denudation rates.  
657

## 658 **6 Conclusions**

659 Soil thickness and properties are investigated in four study areas along a climate  
660 and vegetation gradient. The visually observed transition from mobile soil to  
661 immobile saprolite coincides with one or more changes in measured physical and  
662 chemical properties in each study area. These physical and chemical properties in  
663 turn, influence return-signals generated by Ground Penetrating Radar (GPR) in the  
664 sub-surface, but no systematic trend is visible for which physical or chemical  
665 properties correlate with GPR based observations of soil thickness. Given this, the  
666 measurements and interpretation of GPR signals for systematically identifying

667 subsurface changes in physical and chemical properties is not straightforward and  
668 differs for each study area. In general, the better developed the soil the better the  
669 correlation of GPR signals from point locations with physical and chemical soil  
670 properties. We note that what frequency GPR antenna is best suited for identifying  
671 soil thickness is difficult, and calibration to local point locations (e.g. pedons) is  
672 always required. However, after local calibration between GPR signals and point  
673 locations is conducted, information of soil thickness from point locations can be up-  
674 scaled to hillslope transects with care.  
675

676 ***Acknowledgement***

677 We would like to thank CONAF and all the Park Rangers for the possibility of working  
678 in the natural parks, for providing access to the sample locations, and help inside  
679 the National Parks. We acknowledge support from the German Science Foundation  
680 (DFG) priority research program SPP-1803 “EarthShape: Earth Surface Shaping by  
681 Biota” (sub grants KR 3725/1-1 and SCHA 1690/3-1). RD was supported by a DFG  
682 Emmy Noether grant (DR 822/3-1).

#### 854 **Figure captions**

855 Fig. 1:

856 Digital elevation model (Data source: GTOPO30) for the Chilean Coastal Cordillera  
857 and the Central Andes showing the four investigated study areas (from N to S): Pan  
858 de Azúcar (~26° S); Santa Gracia (~30° S); La Campana (~33° S); and Nahuelbuta  
859 (~38° S).

860

861 Fig. 2:

862 Satellite images (Data source: Google Earth©) of the four study areas from N to S  
863 in latitude: A) Pan de Azúcar; B) Santa Gracia; C) La Campana; and D) Nahuelbuta.  
864 Red stars indicate the pedon positions whereas the blue lines represent the  
865 locations of the geophysical investigations.

866

867 Fig. 3:

868 N- and S-facing hillslopes of the four study areas with locations of soil pedons and  
869 transects of ground penetrating radar indicated by the red double arrows.

870

871 Fig. 4:

872 Compilation of physical and chemical investigations with depth at the pedon location  
873 in the mid-slope position of the S-facing hillslope in Pan de Azúcar. Properties  
874 shown are: 1) GPR transect and the envelope profile of the 500 MHz measurement;  
875 2) GPR transect and the envelope profile of the 1000 MHz measurement; 3) Bulk  
876 density; 4) Grain size distribution of sand, silt, and clay; 5) Loss on ignition LOI; 6)  
877 Chemical index of alteration CIA 7) Chemical index of the mass transfer coefficient  
878  $\tau$ ; and 8) volumetric strain  $\epsilon_{\text{strain}}$ . The black line indicates the boundary between  
879 the mobile soil and the immobile saprolite (after Oeser et al., 2018) and the gray  
880 area with green lines reflects the transition zone from B to C horizon (after Bernhard  
881 et al., 2018).

882

883 Fig. 5:

884 Primary component analysis PCA of properties for all four soil pedons in Pan de  
885 Azúcar. A) Scree plot showing the percentage of explained variances and B)  
886 Variables - PCA.

887

888 Fig. 6:

889 Compilation of physical and chemical investigations at the pedon location in the mid-  
890 slope position of the S-facing hillslope in Santa Gracia. Properties shown are listed  
891 in caption of Fig. 4.

892

893 Fig. 7:

894 Primary component analysis PCA of properties for all four soil pedons in Santa  
895 Gracia.

896

897 Fig. 8:

898 Compilation of physical and chemical investigations at the pedon location in the mid-  
899 slope position of the S-facing hillslope in La Campana. Properties shown are listed  
900 in in caption of Fig. 4.

901

902 Fig. 9:

903 Primary component analysis PCA of properties for all four soil pedons in La  
904 Campana.

905

906 Fig. 10

907 Compilation of physical and chemical investigations at the pedon location in the mid-  
908 slope position of the S-facing hillslope in Nahuelbuta. Properties shown are listed  
909 as in caption of Fig. 4. Note that only the 500 MHz signal and envelope profile exist.

910

911 Fig. 11:

912 Primary component analysis PCA of properties for all four soil pedons in  
913 Nahuelbuta.

914

915 Fig. 12:

916 A) 1000 MHz GPR transect and B) envelope for the S-facing hillslope in Pan de  
917 Azúcar. The hillslope transect spans over ~20 m and includes pedon AZPED60,  
918 AZPED50, and AZPED40 (black boxes). The potential soil thickness based on the  
919 envelopes is indicated by stars (in B). The red bar indicates the B to C horizon  
920 transition as given in Bernhard et al. (2018). Uphill is from left to right. Note that in  
921 the radar data the air wave and background removal is applied.

922

923 Fig. 13:

924 1000 MHz GPR signal and envelope for the mid-slope position of the S-facing  
925 hillslope position in Santa Gracia (SGPED40). The hillslope transect spans over ~20

926 m. Interpretation of the radar signal are indicated where possible (stippled lines in A  
927 and B). The potential soil thickness is indicated based on the envelope profile. Uphill  
928 is from left to right. Lines and symbols in figures as described in Fig. 12.

929

930 Fig. 14:

931 500 MHz GPR signal and envelope for the mid-slope position of the S-facing  
932 hillslope in La Campana (LCPED20). The hillslope transect spans over ~8 m.  
933 Interpretation of the radar signal are indicated where possible (stippled and black  
934 lines in A and B). The potential soil thickness is indicated based on the envelope  
935 profile. Uphill is from left to right. Lines and symbols in figures as described in Fig.  
936 12.

937

938 Fig. 15:

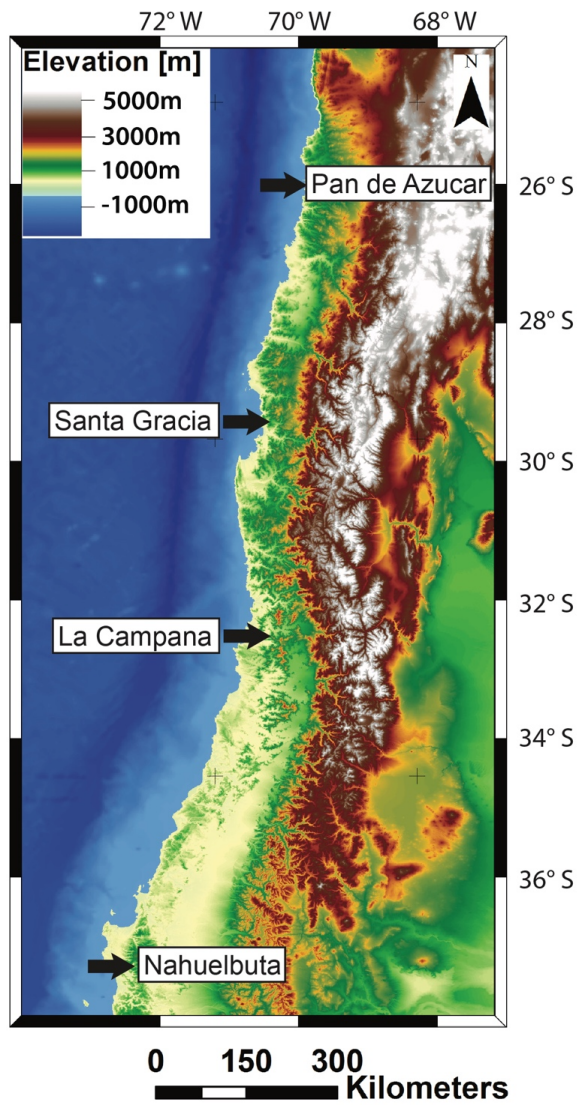

939 500 MHz GPR signal and envelope for the mid-slope position of the S-facing  
940 hillslope in Nahuelbuta (NAPED20). The hillslope transect spans over ~20 m.  
941 Interpretation of the radar signal are indicated where possible (stippled lines in A  
942 and B). The potential soil thickness is indicated based on the envelope profile. Uphill  
943 is from left to right. Lines and symbols in figures as described in Fig. 12.

(1) Depth of BC-horizon transition from Bernhard et al., 2018  
 (2) Depth of mobile layer from Schaller et al., 2018  
 (3) Depth of mobile layer from Oeser et al., 2018  
 (4) Depth based on data from Dal Bo et al., 2019  
 (5) Depth based on single point GPR envelopes (This study)  
 (6) Average depth based on envelopes from GPR transect data (This study)
