14 **Abstract**

15 Over the last century, human activities have induced significant land-cover changes that have
16 accelerated soil erosion processes around the world. In New Caledonia, a French island located in the
17 south-west Pacific Ocean, open-cast nickel mining has raised many concerns regarding its impact on
18 riverine systems (i.e. hyper-sedimentation, overburden) and the island's ecosystems (i.e. flooding,
19 lagoon siltation, water pollution).

20 A sediment tracing study has been conducted to quantify the contribution of mining versus
21 non-mining sub-catchments in one of the first areas exploited for nickel mining, the Thio River
22 catchment (397 km²). Sediment deposited during two cyclonic events (i.e. 2015 and 2017) was
23 collected following a tributary design approach. Source (n= 24) and river sediment (n= 19) samples
24 were analyzed by X-ray fluorescence and spectroscopy in the visible spectra (i.e. 365-735 nm). Four
25 fingerprinting approaches based on (1) colour parameters, (2) geochemical properties, (3) colour
26 parameters coupled with geochemical properties and (4) the entire visible spectrum were tested to
27 estimate sediment source contributions.

28 The results demonstrated that the individual sediment tracing methods based on spectroscopy
29 measurements (i.e. (1) and (4)) did not provide sufficient discrimination between sources. However,
30 the inclusion of colour properties in addition to geochemical parameters (3) provided the highest
31 discrimination between sources (i.e. 92.6 % of source variance explained). Although with a slightly
32 lower discrimination potential (i.e. 83.1 % of variance explained in sources), the geochemical
33 approach (2) provided similar results to those obtained with the colour coupled with geochemical
34 approach (3). In addition, mixed linear models associated with these two approaches have been
35 experimentally validated with artificial mixture samples. The results obtained with model (3) showed
36 that mining source contributions strongly dominated the sediments inputs with a mean contribution
37 of 68 % (SD 25 %) for the 2015 flood event and 88 % (SD 8%) for the 2017 flood event. These results
38 suggest that catchment management should focus on the contributions of mining tributaries to

39 reduce sediment inputs in the river systems. Therefore, the use of these approaches based on
40 geochemical properties individually (2) and coupled to colour parameters (3) could be extended to
41 other mining catchments of New Caledonia but also to other similar nickel mining catchments
42 around the world (e.g. Australia, Brazil, Dominican Republic, Cuba) to estimate sediment source
43 apportionment.

47 Introduction

48 At the dawn of a fourth industrial revolution, demand for metalliferous minerals continues to
49 increase and impact the world market (Prior et al., 2013;Highley et al., 2004). Currently, open-cast
50 mining generates more than three-quarters of the world's metal ores. However, the extraction of
51 these minerals is associated with deleterious impacts on the environment. In particular, these mines
52 are responsible for the increase in soil erosion and the transfer of sediment in river systems
53 worldwide (Yellishetty et al., 2013;Dumas et al., 2010;Abel et al., 2000).

54 New Caledonia, an island located in the south-western Pacific Ocean and currently the world's
55 sixth-largest producer of nickel, is in particular challenged with the problems of hyper-sedimentation
56 and over-burden of its river systems. Several studies outline how mining activities, which started in
57 1875, are generally responsible for these deleterious river morphological changes (Bird et al.,
58 1984;Iltis, 1992;Garcin et al., 2017). The excessive sediment inputs transferred mainly during
59 extreme rainfall events (e.g. cyclones and tropical depressions) lead to the increased occurrence of
60 flooding events in these tropical regions. Owing to the occurrence of major cyclones in New
61 Caledonia (i.e. on average one cyclone every 2.7 years (Garcin, 2010)), the local population regularly
62 have to deal with the damage generated by these flood events (e.g. damage to human settlements,
63 public infrastructure, agricultural land and, human casualties). Moreover, the island's agricultural and
64 fishing resources are also impacted.

65 Suspended sediment is known to transport large quantities of contaminants in river systems
66 (Vaithiyathan et al., 1993;Bradley and Lewin, 1982). Hedouin et al. (2007), and more recently
67 Baudrimont et al. (2019), observed high concentrations of trace metals, including Ni and Cr, in
68 marine and freshwater organisms in New Caledonia. On a more global level, this anthropogenic
69 activity also threatens the second largest coral reef in the world, listed as a UNESCO World Heritage
70 In particular, the increased turbidity associated with sediment supply could disrupt coral metabolism
71 (i.e. photosynthetic processes) (Juillot, 2019). These coral reefs provide an exceptional biological

72 diversity and deliver several essential ecosystem services to the local population including fisheries,
73 coastal protection and tourism (Pascal, 2010). The implementation of effective and perennial
74 sediment control measures on mining sites (e.g. sediment retention basin, revegetation) is therefore
75 required to reduce sediment inputs into the lagoon.

76 Erosion generated by open-cast nickel mining (i.e. mining bare soil, mining roads, mining
77 prospection and mining waste) do not provide the only sediment source in New Caledonia's mining
78 catchments. The use of fires to clear landscapes conducted by the local population for farming,
79 pasture and hunting increase the area of bare soils (Dumas et al., 2010). Soils that are left uncovered
80 by vegetation are more sensitive to erosion and they may be exposed to shallow landsliding (Blake et
81 al., 2009; Smith et al., 2011). Moreover, several invasive species such as deers or wild pigs also
82 threaten soil stability through trampling and overgrazing (Shellberg et al., 2010).

83 The contribution of mining tributaries (i.e. draining mining areas) and non-mining tributaries
84 (i.e. draining areas without mining activities) to sediment transiting catchments in New Caledonia
85 therefore needs to be discriminated. This discrimination has particularly become important since the
86 mining industries are subject to the "polluter pays" principle applied since 1974. The obligation to
87 fund remediation according to the extent of the damage generated by mining activity on the
88 environment. There is therefore a real social, environmental and financial challenge in discriminating
89 between sediment sources generated by mining activities and other potential sediment sources.

90 Sediment fingerprinting techniques have been developed since the 1970s to determine the
91 spatial origin of sediment sources and quantify their contributions (Collins et al., 1996; Walling et al.,
92 1979). These techniques are based on the analysis of multiple conservative properties both in the
93 sediments and their potential sources. Fallout radionuclides (Wallbrink, 2004; Evrard et al.,
94 2015; Wallbrink et al., 1998; Evrard et al., 2020), geochemical (Collins et al., 1997; Laceby and Olley,
95 2015) and mineral properties (Klages and Hsieh, 1975; Walden et al., 1997) are the most frequently
96 used tracers to quantify sediment source contributions. The use of fallout radionuclides and

geochemical properties as potential tracers was investigated to quantify the sources of suspended sediment in the Thio River catchment (397 km²), one of the first catchments in New Caledonia to be mined for nickel. Geochemical properties provided promising results (i.e. 83.1 % of variance explained in sources) while the fallout radionuclides proved to be unsuitable (i.e. non-discriminatory) (Sellier et al., 2019). However, other less expensive, faster and possibly more efficient techniques than the more conventional methods previously tested could be envisaged. For example, spectroscopy in the mid-infrared (MIR) (Poulenard et al., 2009), the visible near-infrared (VNIR) and the shortwave-infrared (SWIR) (Brosinsky et al., 2014) regions of spectra have been used to quantify the sediment source contributions. It is also non-destructive and requires low quantities of sample material. Spectroscopy could therefore meet both the need for a simple and rapid sediment tracing method in a context where flood events are frequent.

Moreover, New Caledonia has a specific geological feature which is at the origin of its mineral wealth: one third of its surface area is covered with peridotite massifs. The weathering of these rocks enriched in Fe and transition metals such as Mn, Ni, Cr and Co results in the formation of Ni- and Fe-rich smectite, serpentine, goethite and hematite. The oxidized minerals (i.e. goethite and hematite) provide a particularly reddish-orange colour to mining sources that distinguishes them from non-mining sources, which tend to be grey in colour. The differences made visually between the two sources further encourage the analysis of sources by spectroscopy and especially spectroscopy in the visible region of the spectrum (i.e. 365-735 nm). In particular, the colorimetric parameters derived from the visible spectrum have been shown to be effective in discriminating sediment sources. Their discrimination power has been tested both individually (Evrard et al., 2019; Martínez-Carreras et al., 2010; Uber et al., 2019) and in combination with other tracers (e.g. geochemical properties (Tiecher et al., 2015)) according to the conventional fingerprinting approach (i.e. statistical analysis and use of a mixing model). A more alternative approach based on the entire visible spectrum with the partial least square regression (PLSR) models has also been developed to trace origin of sediment sources in the literature (Legout et al., 2013; Tiecher et al., 2015).

As part of this study, four sediment fingerprinting methods based on (1) colour parameters, (2) geochemical properties, (3) colour parameters coupled with geochemical properties and (4) PLSR models based on the whole visible spectrum were tested in the Thio River catchment. Source (n=24) and river sediment (n=19) samples were collected following a tributary design approach and analyzed by X-ray fluorescence and spectroscopy in the visible spectra (i.e. 365-735 nm). The performance of each method to estimate sediment source contributions was evaluated in order to select the best technique to be applied in the Thio River catchment and possibly in other mining catchments of New Caledonia. On a wider scale, the tracers retained in this study could be considered as potential sedimentary tracers to estimate sediment source apportionment in other similar nickel mining catchments around the world (e.g. Australia, Brazil, Dominican Republic, Cuba).

Materials and methods

1.1. Study area

Located in the southwestern Pacific Ocean, New Caledonia (18 500 km²) is made up of several islands, the largest of which is *La Grande Terre* (17 000 km²). The Thio River catchment (397 km²) is located on the east coast of this island (Figure 1-a). It has a mountainous relief, with an average altitude of 416 m above sea level (i.e. minimum: 0 m, maximum: 1392 m, Figure 1-a) and an average slope of 45%. Two dominant lithologies are present in the catchment: volcano-sedimentary formations mainly located on the western part of the catchment and peridotite massifs concentrated in the eastern part of the catchment. Cherts (22 %), sandstone (9 %), a mix of basalt, dolerite and gabbro (6 %), polymetamorphic rocks (6 %) mainly constitute volcano-sedimentary formations whereas peridotite massifs are composed of laterites (18 %), peridotites (17 %), serpentines (10 %) and hazburgites (1 %) (Garcin et al., 2017) (Figure 1-b). The Thio River catchment is covered on 96% of its surface by permanent vegetation. According to the mining registry, active and abandoned mining sites and exploration cover 21 % of the catchment area (Figure 1-c).

147 The Thio River catchment is subject to a tropical climate characterized by the alternation of a
148 hot wet season (November-April; mean temperature of 27 °C) and a cooler dry season (May-October;
149 mean temperature of 20 °C). The mean annual rainfall in the Thio River catchment is 1620 mm
150 despite strong seasonal fluctuations with the highest levels of precipitation recorded during the
151 cyclonic season between January and March (700 mm, 1981-2008; Alric (2009)). Although they only
152 occur on average once every 2.7 years, cyclones or tropical depressions may supply more than 20 %
153 of the annual rainfall in only one day according to local meteorological records (Météo France).

154
155 Twelve major tributaries flow into the main stem of the Thio River (28 km long) (Figure 1-b).
156 Ninety-two percent of the river channel length are characterized with slopes lower than 5 %.
157 According to Surell's classification (Surell, 1984), the Thio River can be considered as torrential except in its
158 estuarine section. In addition, the extensive bare soil surface associated with past mining activities
159 (~10 sites), ongoing mining operations (e.g. 2 sites: Thio Plateau, Camps des Sapins) and the
160 occurrence of 6 km² of mining roads exacerbate runoff production as they contribute to increased
161 river network connectivity (Alric, 2009). This generates extensive erosion processes that are evident
162 across the entire Thio catchment with the widespread occurrence of rills, gullies, landslides and
163 channel bank erosion (Danloux and Laganier, 1991).

164

165

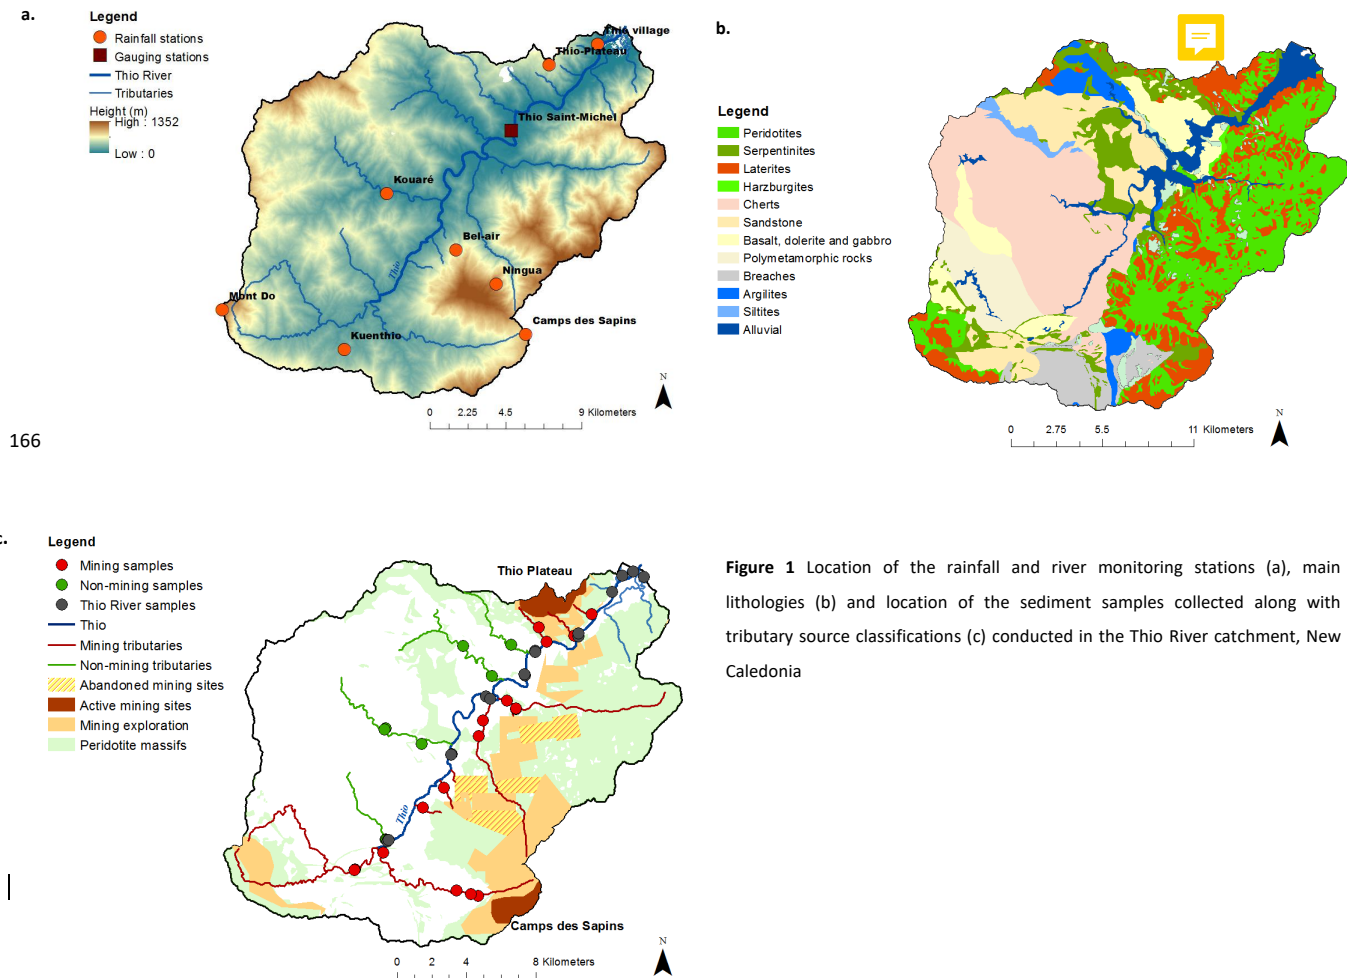

Figure 1 Location of the rainfall and river monitoring stations (a), main lithologies (b) and location of the sediment samples collected along with tributary source classifications (c) conducted in the Thio River catchment, New Caledonia

1.2. Hydro-sedimentary monitoring

Three rainfall stations (Thio Plateau, Thio village, Camps des Sapins; Figure 1-b) are operated by Météo France and five others are managed by the DAVAR (Direction des Affaires Vétérinaires Alimentaires et Rurales; i.e. Kouaré, Bel-Air, Ningua, Kuenthio, Mont Do), with daily records available since 1952 for some stations (e.g. Thio village). Daily discharge has been monitored at a river gauging station located on the main stem of the Thio River (at Saint-Michel) since 1981 by the DAVAR (Figure 1-a).

1.3. Sources and river sediment sampling

To trace the origin of sediment, lag deposits were collected as an alternative of suspended sediment sampling on channel bars of mining tributaries ($n = 16$), non-mining tributaries ($n = 8$) and the Thio River ($n = 19$) according to the tributary approach recommended by Laceby et al. (2017) (Figure 1-c). They were sampled after two major floods (~10 year return period): (1) the tropical depression of February 25, 2015 ($n = 31$) and (2) Cyclone Cook on April 10, 2017, ($n = 1$). These two sample sets were respectively sampled between April 30 and May 5, 2015 and between May 16 and May 17, 2017. At each sampling site, five to ten subsamples of fine sediment were collected across a 10 m² surface with a plastic trowel at exposed subaerial sites free of vegetation on channel bars. The subsamples were composited into one sample representative of the fine sediment deposited on the channel bars. The samples were oven-dried at 40°C for ~48 hours and sieved to 63 µm.

1.4. Preparation of artificial mixture samples

Equal quantities of all mining source samples ($n = 16$) were collected and mixed together to create a composite sample of mining sources. The same process was carried out with non-mining source samples ($n = 8$). The two composite samples respectively corresponding to mining and non-mining sources were then mixed in known proportions to create artificial mixture samples ($n = 21$, 0-100 % with a 5 % step, Table 1).

Table 1 Proportions of mining and non-mining sources (%) in artificial mixture samples (M_i). M_6 was withdrawn from this study because an error occurred at the time of its completion (out of study).

M_i	Proportions of mining sources (%)	Proportions of non-mining sources (%)
M1	0	100
M2	5	95

M18	85	15
M19	90	10
M20	95	5
M21	100	0

1.5. Source, river sediment and artificial mixture sample analyses

A portable diffuse reflectance spectrophotometer (Konica Minolta 2600d) was used to measure the spectra in the visible (365–735 nm with a 10-nm resolution, 39-wavelength class) of Thio River sediment ($n = 19$), tributary source ($n = 16$) and artificial mixture samples ($n = 20$). Sample quantities between 0.1 g and 4 g were stored in 60 mL polystyrene tubes and analyzed at the Institut des Géosciences de l'Environnement (IGE, Grenoble, France). Because of the rather small measuring area (i.e. 3-mm radius circle), and to take into account the possible heterogeneity within the samples, three measurements were carried out on river sediment and sources samples. For artificial mixture samples, the experimenter who conducted the analyses carried out four measurements. Several parameters (i.e. D65 illuminant, 10° angle observer and specular component excluded) were

206 applied for each measurement. Raw data collected corresponds to the spectral reflectance
 207 percentage for each of the 39-wavelength class. From these raw data, 15 variables of various
 208 colorimetry models were derived. Among these components, XYZ tri-stimulus values were calculated
 209 based on the colour-matching functions defined by the International Commission on Illumination (CIE
 210 1931). The standardized tri-stimuli were then converted into CIELab and CIELu'v' cartesian coordinate
 211 systems using the equations provided by CIE (1976) and then into CIELch, CIEL*a*b* cartesian
 212 coordinate systems using the equations provided by CIE (1994) (Rossel et al., 2006). First Derivative
 213 reflectance of the Visible Spectra (FDVS) of each sample was also derived from the initial reflectance
 214 spectrum. According to Tiecher et al. (2015), the use of FDVS avoids differences in baseline positions
 215 and to get rid of the small differences due to uncontrolled sources of variation, as sample packaging.

216 Measurements of 11 geochemical elements (i.e. Mg, Al, Si, K, Ca, Ti, Cr, Mn, Fe, Ni and Zn) on
 217 the samples were conducted by pre-calibrated energy dispersive X-ray fluorescence spectrometry
 218 (Epsilon 3, Malvern PANalytical) with certified reference samples including Internal Atomic Energy
 219 Agency (IAEA) standards ($r^2 = 0.90-0.99$, mean relative error: 9%, SD 8 %, minimum: 1%, maximum:
 220 23%). Between 0.2 and 0.5 g of the samples were packed in small mass holder (SMH) cells with an air
 221 double X-ray Mylar film and analyzed at the Laboratoire des Sciences du Climat et de
 222 l'Environnement (LSCE, Gif-sur-Yvette, France). Samples were irradiated with a primary beam
 223 generated by an Rh anode X-ray tube emitting electromagnetic waves between 100eV and 1MeV
 224 with a maximum power, typical current and voltage fixed to 15 W, 3mA and 50 kV respectively. The
 225 associated Si-drift detector had a Be window thickness of 8 μm and recorded the sample spectrum in
 226 a 2D optical geometry configuration. X-ray intensities were converted into concentrations using the
 227 Epsilon 3 software program through the application of the fundamental parameters method.

228 1.6. Statistical analysis and sediment tracing

229 1.6.1. Conventional mixing model

230 In general, the sediment source fingerprinting approach is composed of four main steps: (1)
 231 range test, (2) the Mann-Whitney U test, (3) a stepwise discriminant function analysis and (4) a
 232 mixing model (Collins et al., 1996). For the range test, all variables exhibiting values in the river
 233 sediment samples that were outside of the range found in the potential sources (i.e. between the
 234 minimum and maximum values found in source samples) were excluded from the analysis. It is
 235 important to restrict the tracing parameters to those that show a conservative behavior to avoid
 236 incorrect source prediction and consequently inaccurate estimations of source contributions (Sherriff
 237 et al., 2015). Thereafter, the Mann-Whitney U test ($\alpha = 0.05$, p-value < 0.01) was performed to
 238 evaluate whether remaining variables could discriminate the source samples. A stepwise
 239 discriminant function analysis (DFA) was independently run on three set of potential tracing
 240 properties: (1) colour parameters (i.e. 'colour'), (2) geochemical properties (i.e. 'geochemistry') and
 241 (3) colour parameters and geochemical properties (i.e. 'colour + geochemistry'). For the last set, the
 242 raw values of the variables were normalized in order to make them comparable. Indeed, several
 243 colour parameters were within an order of magnitude of around 0.01 whereas for the geochemical
 244 parameters the difference was around 10^6 mg kg^{-1} which resulted in a poorly conditioned matrix for
 245 the DFA.

246 The following calculation was therefore applied on the variable values to normalize them: $x_i -$
 247 $x_{\min} / x_{\max} - x_{\min}$ where x_i was value found in source sample (i), x_{\min} and x_{\max} were respectively the
 248 minimum and maximum values found in the source samples. The DFA was carried out to select the
 249 optimal number of potential tracers to discriminate the sources for each modelling approach with
 250 the optimal number of potential tracers which must provide the lowest Wilks' lambda value from
 251 analysis of variance. Indeed, the closer the Wilks' lambda value is to 1, the lower the variability within

252 the sources compared to the total variability. The DFA was performed in the backward mode with a p
 253 >0.01 used to select a tracer and p <0.01 used to remove a tracer.

254 Finally, a classical solver-based mixing model was used to model the source contributions from
 255 the mining and non-mining tributaries to target sediment through simultaneously minimizing the
 256 mixing model difference (MMD) (Evrard et al., 2019):

257
$$MMD = \sum_{i=1}^n ((C_i - (A_i x + B_i(1 - x))) / C_i) \text{ Equation 1}$$

258 where n is the number of parameters in the model chosen by the selection process (i.e. steps 1, 2, 3);
 259 C_i is the Thio River sediment sample parameter (i); x and (1-x) were respectively the contributions of
 260 source A and B (i.e. mining and non-mining tributaries); A_i is the mean of parameter (i) in source A
 261 and B_i is the mean of parameter (i) in source B. The proportional contribution from each source (x)
 262 was modelled by solving Equation 1 with the Solver Function in Microsoft Excel with x being between
 263 0 and 1 and the sum of source contributions (i.e. x and 1-x) equaling 1. The GRG Non-Linear solving
 264 method was used with automatic scaling in Solver, ignoring integer constraints, with a maximum run
 265 time of 5000 and allowing for 2500 iterations. A multi-start population size of 2500 was used along
 266 with the same random seed for each of the model runs while requiring bounds on the variables. A
 267 constraint precision and convergence of 1.0E-05 were selected. To test the reliability of the 'colour',
 268 'geochemistry' and 'colour + geochemistry' models, these latter were tested on artificial mixture
 269 samples.

270 1.6.2.FDVS- PLSR model

271 FDVS-PLSR models were built following the methodology described in Poulenard et al. (2012).
 272 The first step consisted in applying a principal component analysis (PCA) to evaluate the overall
 273 variability between FDVS (i.e. 38 wavelengths) of source samples. Subsequently, a discriminant
 274 analysis (DA) was conducted based on the PCA scores. The purpose of this analysis was to compare
 275 the Mahalanobis distance between sources samples and to determine if FDVS of source samples

could discriminate the sources. Relationships between FDVS (x variate) and the corresponding weight contribution of the sediment source data sets (y variate) were analyzed using PLSR. The PLSR models were carried out based on the component set providing the lowest predictive error (PRESS, option on XLStat software). Two independent PLSR models were built to estimate the two sediment source contributions. As the artificial mixtures were measured four times by spectroscopy, 84 FDVS of artificial mixture samples were generated including 50 values that were randomly selected to build the models (training set (ST)) and 34 to validate the models (validation set (SV)). The SV:ST ratio used was approximately 1:2, which is in agreement with recommendations provided in the literature (Daszykowski et al., 2002). To evaluate the performance of PLSR models, several indicators such as coefficient of linear regression (r^2), root mean square error of calibration (RMSEC) and root mean square error of prediction (RMSEP) values were calculated. Unlike the conventional fingerprinting approach, the estimated contributions of sources were not limited to be in the range of 0 % and 100 %. In a similar way, the sum of source contributions was not constrained to be equal to 100 %. As a result, another way to control the reliability of predictions was to sum the prediction proportions of both models (Legout et al., 2013). FDVS of river sediment samples were then introduced into these PLSR models to estimate the contribution of sediment sources.

Results

1.7.Source description

The ranges of values of all colour parameters measured in the Thio River sediment samples systematically plotted within the range of values observed in the two potential sources (i.e. mining and non-mining tributaries; Figure 2 and Table 2). The range test results confirmed the conservative character of these parameters. For geochemical properties, elemental concentrations measured in the river sediment also plotted within the range of concentrations found in sources (Sellier et al., 2019). According to the range test results, all properties were determined to be conservative.

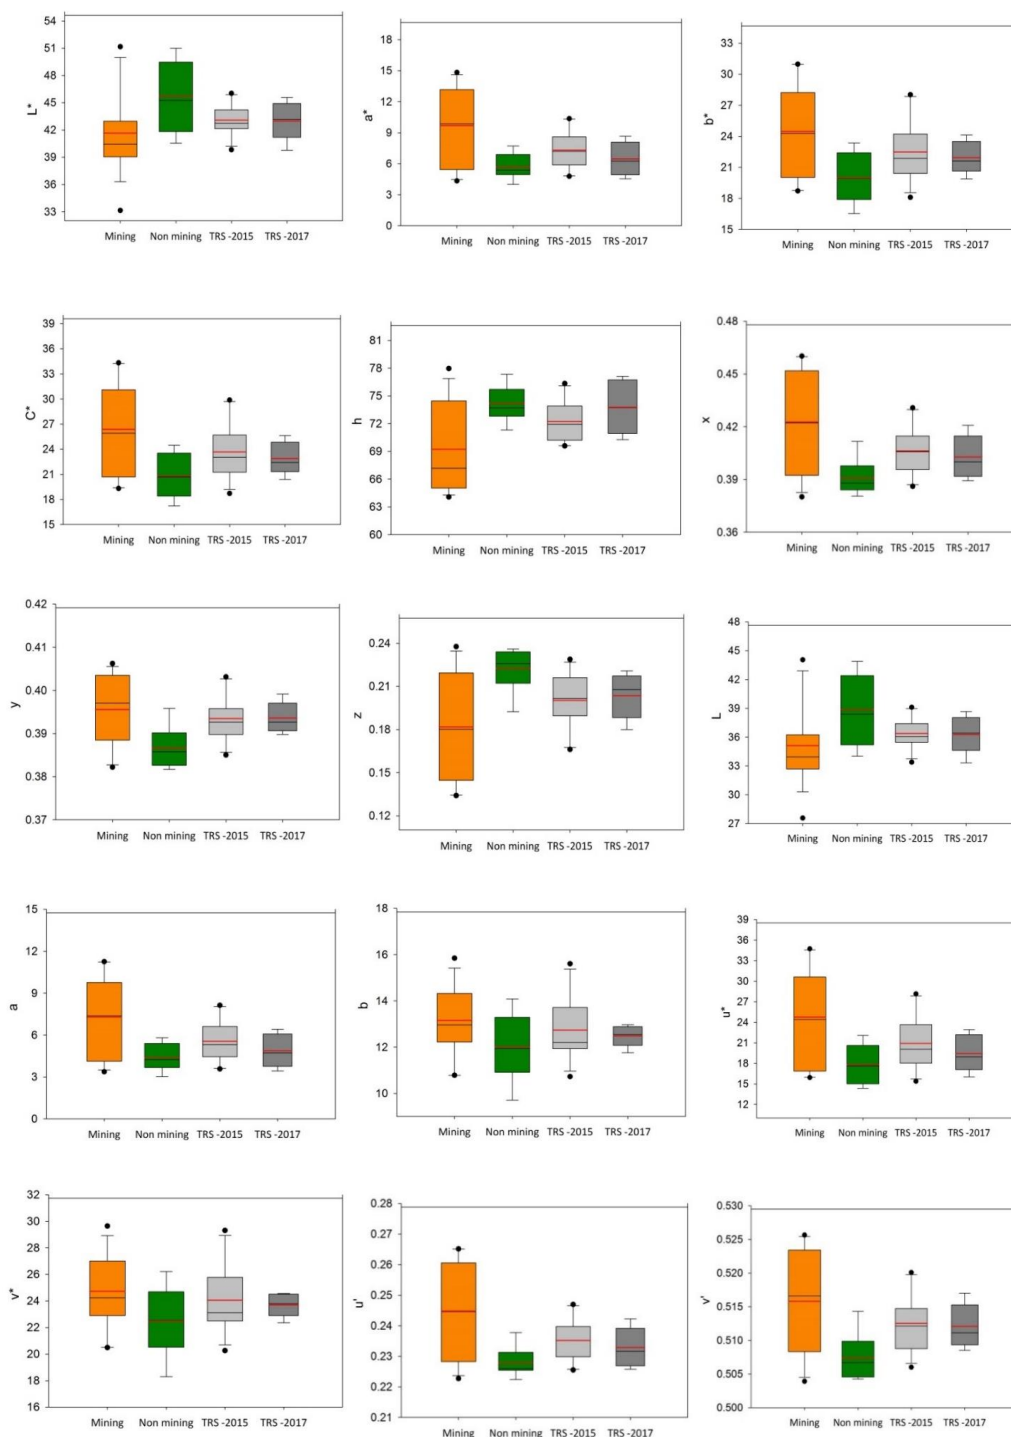

Figure 2 Box-plots of colour parameter values in the <63 μ m fraction of sediment collected on the mining tributaries (Mining), non-mining tributaries (Non-mining) and the main Thio River (Thio River sediment (TRS)-flood events of 2015 and 2017). The box indicates the location of the first and third quartiles; the black line indicates the median value; the red line indicates the mean value

1.8. Selection of parameters/properties for modelling

1.8.1. 'Colour' model

According to the Mann-Whitney U test results, six colour parameters (*i.e.* b^* , C^* , x , y , z , v') provided significant discrimination between the two sediment sources (*i.e.* p -value < 0.01 , Table 2). The backward DFA selected only v' as the optimal tracer of mining and non-mining source sediments (Figure 2, Table 3). Although this parameter correctly classified 79.2 % of sources, the high Wilk's lambda value obtained (*i.e.* 0.7209, Table 3) induced that only 27.9 % of variance was explained by v' . The low Mahalanobis distance value obtained (*i.e.* 1.6) confirmed that sediment sources were not well separated. Accordingly, and owing to the high error percentage of the source discrimination provided by this approach (*i.e.* 72.1 %), source contributions were not modeled with the 'colour' model.

1.8.2. 'Geochemistry' model

When considering the two potential sediment sources, all geochemical properties (except Zn) were selected as potentially discriminant by the Mann-Whitney U test (*i.e.* p -value < 0.01 , Table 2). Among the 10 potential tracers, 5 were selected by the backward DFA to model sediment source contributions from mining and non-mining tributaries with 95.3 % of sources correctly classified and 83.1 % of variance explained by K. This percentage of variance explained was deduced from the final Wilk's lambda value obtained (*i.e.* 0.1691). Moreover, the Mahalanobis distance value showed that the sediment sources were well separated from each other with a significant distance of 20.3 (Table 3) (Sellier et al., 2019).

1.8.3. 'Colour + geochemistry' model

When combining colour parameters and geochemical properties, the DFA selected five optimal tracers (*i.e.* K, Ca, Ti, b^* , C^*) able to correctly classify 100 % of the sources. A significant improvement in the source discrimination was observed with the lowest Wilk's lambda value obtained (*i.e.* 0.0734) and the highest percentage of variance explained (*i.e.* 92.6 %). Moreover, the Mahalanobis distance

value obtained (i.e. 52.1) was more than 2.5 times higher than that estimated with the 'geochemistry' model (Table 3), thus resulting in a better separation between sediment sources than the previous approach (i.e. 'geochemistry')

Table 3 Results of DFA used to identify the optimum tracer combination to differentiate sources supplying sediment to the Thio River

Fingerprint property selected	Wilks' Lambda	Variance explained by the variables (%)	Squared Mahalanobis distance	Correctly classified samples (%)
'Colour'				
v'	0.7209	27.9	1.6	79.2
'Geochemistry'				
K	0.1691	83.1	20.3	95.3
'Colour + Geochemistry'				
K, Ca, Ti, b*, C*	0.0734	92.6	52.1	100

1.9. Assessment of model performance on artificial mixture samples

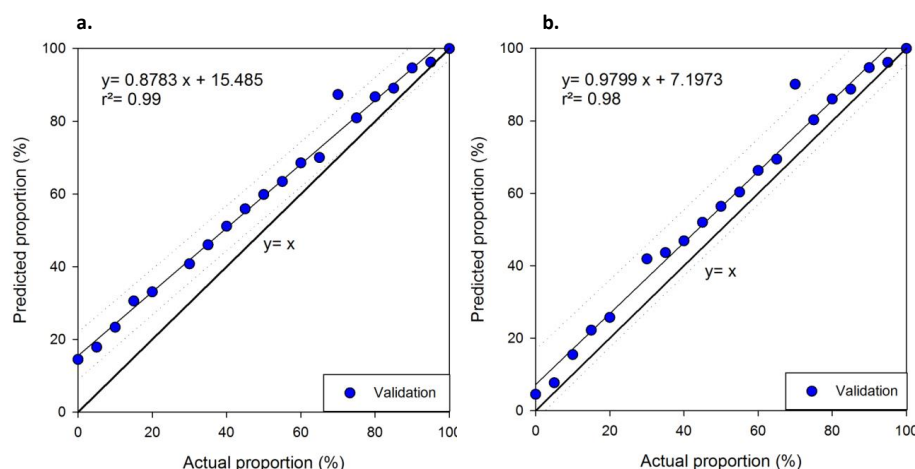

Prior to applying mixing models to river sediments, preliminary tests were conducted to control the validity of the models (i.e. 'geochemistry' and 'colour + geochemistry') and the associated estimations of source contribution errors. When applying these models on the artificial mixture samples, actual and predicted proportions were well correlated for both models (i.e. $r^2 = 0.99$ and $r^2 = 0.98$ respectively for 'geochemistry' and 'colour + geochemistry' models) (Figure 3).

However, the 'geochemistry' model described in Figure 3-a showed that the contributions of mining tributaries were overestimated. With 100 % of actual mining contributions, 100 % of mining contribution was predicted by the model. However, instead of 0 % of actual mining contributions, a mining contribution of 15.5% was predicted by the model. It means that the more the estimated mining source contributions tends towards 0%, the greater the associated overestimation (i.e. maximum 15.5 %) (Figure 3-a). The 'colour + geochemistry' model also provided a slight

overestimation of the contribution of mining tributaries (i.e. 7 % intercept of the regression line,
 Figure 3-b). Given the slope of the regression line calculated is close to 1 (i.e. 0.98), this 7%
 overestimation remains constant over the entire range of potential contributions.

Figure 3 Comparison between actual mining source proportions prepared in artificial mixtures and the mining

source proportions predicted by the 'geochemistry' (a) and 'colour + geochemistry' (b) models

1.10. Building partial least-squares models based on FDVS

Mining sources are characterized by a red-orange color while sediments originating from non-mining sources are grey. The color contrasts may be explained by the distinct geochemical composition of these sources. Mean FDVS indicated the presence of goethite (i.e. at 445 and 525 nm), hematite (i.e. at 555, 565 and 575 nm), and organic matter (i.e. between 600-700 nm) (Debret et al., 2011) in both mining and non-mining sources (Figure 4). In similar way, the Thio River sediment samples (2015, 2017) showed similar characteristics since the variations of the mean FDVS remained between those found in the sources (Figure 4). Nevertheless, some differences can be observed between the sources. The spectral signature of goethite is slightly stronger at 445 nm in non-mining tributaries compared to mining tributaries. No difference between sources was observed at 525 nm, the second wavelengths characterizing the presence of goethite. In contrast, the spectral signature of

hematite (*i.e.* at 555, 565 and 575 nm) was stronger in mining tributaries than in non-mining tributaries.

Figure 4 FDVS measured in the <63 μm fraction of sources and Thio River sediment samples

To test the potential discrimination offered by FDVS, a PCA was applied on the source data set. The first ten principal components from PCA explained 99 % of the total variation in the spectra. The DFA performed on these components resulted in a final Wilks' lambda value of 0.1585. It means that 84.1 % of variance is explained by these ten components. Moreover, 100 % of the source samples were correctly classified. The performances of FDVS-PLSR models are presented in Figure 5. The mining and non-mining tributary FDVS-PLSR models provided an excellent correlation between actual and predicted proportions with r^2 and slopes close to 1 and intercepts of linear regression close to 0. The root mean square error of calibration (RMSEC) values estimated for both models were low, *i.e.* 3.4 % and 3.1 % respectively for mining and non-mining tributary models. These models also

provided a good predictability of source contributions with low root mean square error of prediction (RMSEP) values (i.e. 8.0 % and 4.7 % respectively for mining and non-mining tributary models). Another way to control the reliability of predictions was to sum the predicted proportions of both models (Legout et al., 2013). Considering the whole data set used in the construction of the partial least-squares regression models (i.e. calibration and validation) led to a mean sum of the predicted source proportions of 102 % (SD 3 %, range: 98-114 %), thus highlighting the effective prediction performance of FDVS-PLSR models.

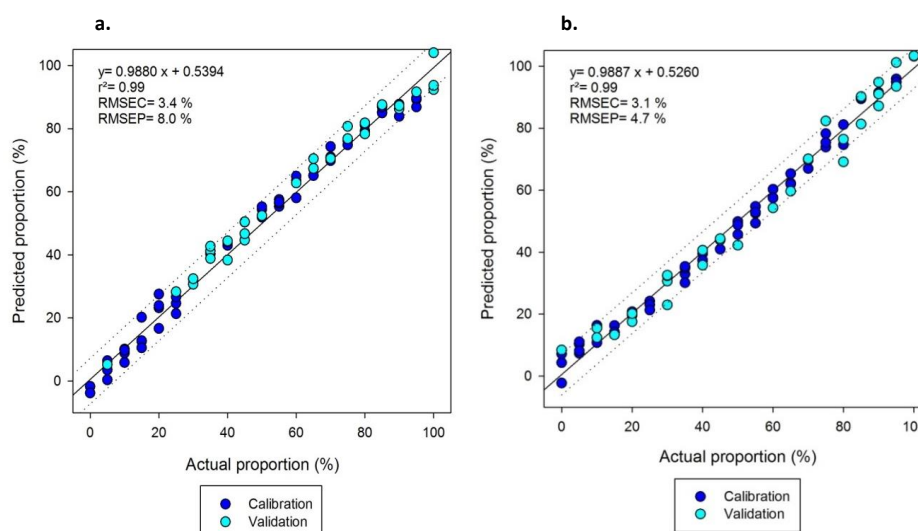

Figure 5 Building of FDVS-PLSR models for mining sources (a) and non-mining sources (b)

1.11. Source apportionment modelling

1.11.1. 'Geochemistry' model

The 'geochemistry' model estimated that the mining tributaries contributed an average of 65 % (SD 27 %) of the Thio River sediment during the 2015 flood event; they therefore dominated sediment inputs overall during this event. Nevertheless, non-mining tributaries locally mainly contributed to the sediment inputs at three sampling points along the Thio River (Figure 6-a, Table 4, sampling points [3, 5, 7]). These contributions did not, however, compensate those provided by

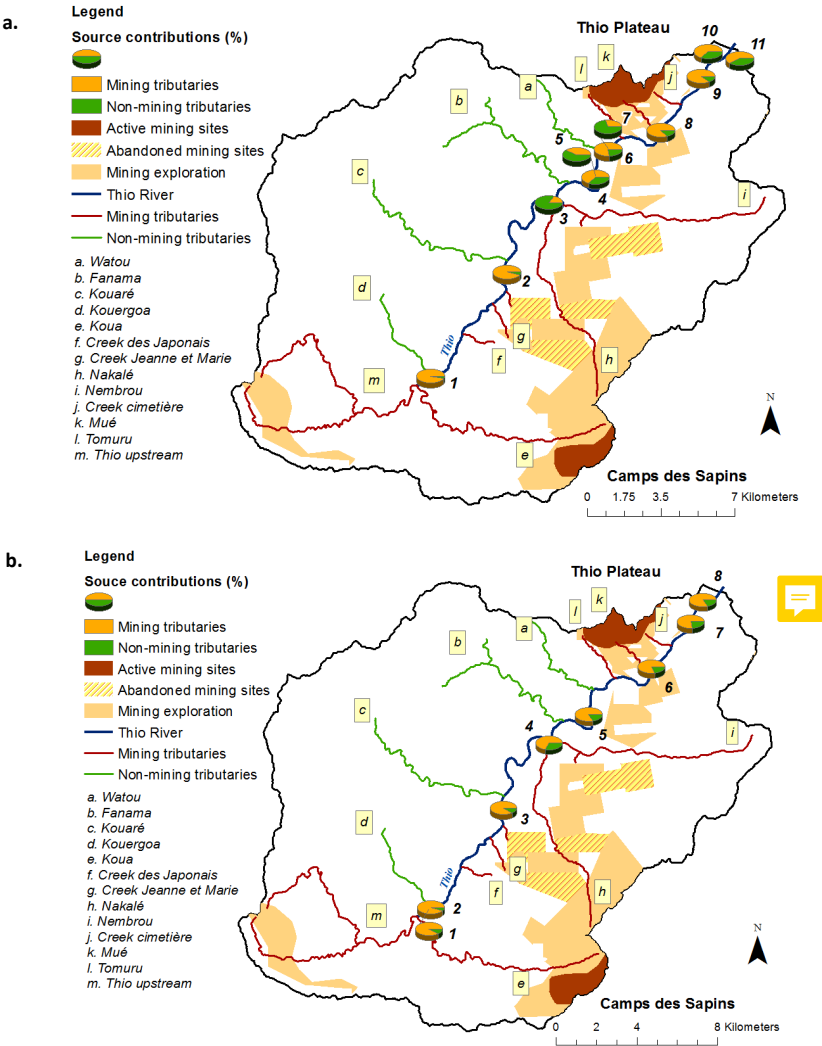

394 mining tributaries in the estuary (63-89 %). Indeed, the dominant mining contributions found in
395 upstream river reaches (96 %, Figure 6-a, Table 4, sampling point [1]) gradually decreased along the
396 Thio River, fluctuating between 17-77 % before increasing again at the confluence between the Thio
397 River and the mining tributaries draining the Thio Plateau mining area (i.e. 85 %, Figure 6-a, Table 4,
398 sampling point [8]) and reaching 60-64 %.

399

400  model also demonstrated that mining tributaries dominated sediment inputs with a mean
401 contribution of 83 % (SD 8%) during the 2017 flood event (Table 5). The lowest mining tributary
402 contributions estimated (i.e. 69 %) was found after the confluence with the Kouaré non-mining
403 tributary (Figure 6-b, Table 5, sampling point [4]). Nevertheless, further downstream, the proportions
404 of the mining sources increased again to reach 77-83 % in the estuary (Figure 6-b, Table 5, sampling
405 points [7, 8]).

406

407 **Figure 6** Relative contributions of mining and non-mining tributaries to the sediment collected in the Thio River
408 during the 2015 (a) and 2017 (b) flood events using the 'geochemistry' model

409

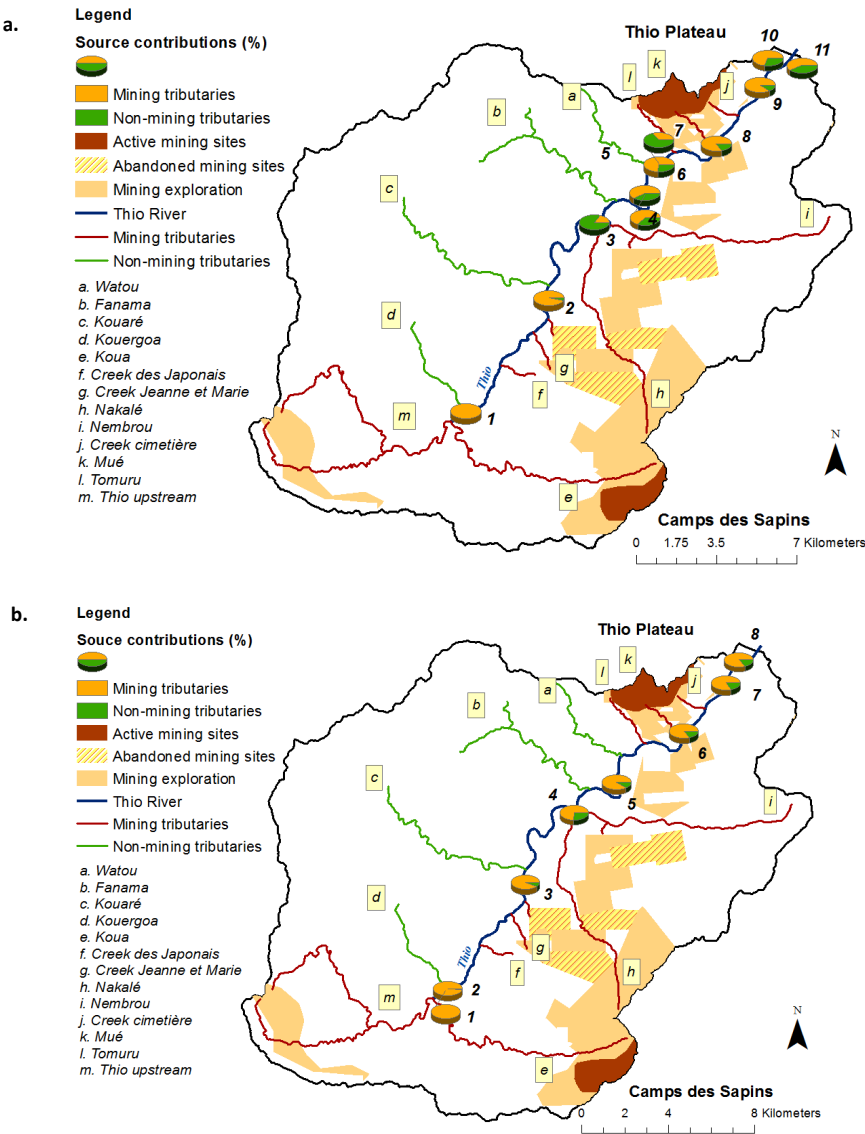

410 1.11.2. 'Colour + geochemistry' model

411 Similar results were obtained with the 'colour + geochemistry' model. The contributions of
412 mining tributaries were estimated to an average of 68 % (SD 25 %) for the 2015 flood event. Mining
413 tributary contributions provided almost all the sediment transiting the uppermost reach of the Thio
414 River (i.e. 99 %, Figure 7-a, Table 4, sampling point [1]). However, after the confluence with the
415 Kouaré tributary, non-mining tributaries dominated with a contribution of 83 % (Figure 7-a, Table 4,
416 sampling point [3]). Further downstream, the contribution of mining tributaries increased again with
417 supplies varying between 34- 89 % to reach 58- 70 % in the estuary (Figure 7-a, Table 4). The largest
418 difference between 'geochemistry' and 'colour + geochemistry' model outputs was 18 % for the 2015
419 flood event.

420 The 'colour + geochemistry' model also demonstrated that 88 % (SD 8 %) of the sediment
421 supply originated from mining tributaries during the 2017 flood event. Along the Thio River, mining
422 tributary contributions varied between 100 % in the uppermost reach, 74% after the Kouaré river
423 confluence and 83-85% in the estuary (Figure 7-b, Table 5). The largest difference between
424 'geochemistry' and 'colour + geochemistry' model outputs was 10 % for the 2017 flood event (Table
425 5).

426

427 **Figure 7** Relative contributions of mining and non-mining tributaries to the sediment collected in the Thio River
428 during the 2015 (a) and 2017 (b) flood events using the ‘colour + geochemistry’ model

429 1.11.3.FDVS-PLSR model

430 When applying the FDVS-PLSR models (i.e. mining and non-mining tributary contributions) to
 431 the river sediment samples (2015, 2017), the mean sums of the source contributions were 92 % (SD 8
 432 %) and 80 % (SD 13 %), respectively, for the 2015 and 2017 flood events (Tables 4 and 5). Owing that
 433 predicted sums were different from the expected 100%, a bar plot display of the source contributions
 434 has been chosen to facilitate the interpretation of the results (Figure 8).

435 According to the FDVS-PLSR model results, 34 % (SD 22 %) of sediment supply originated from
 436 mining tributaries while non-mining tributary contribution provided 58 % (SD 18 %) of the sediment
 437 input for the 2015 flood event (Figure 8-a, Table 4). In the upper part of the Thio River catchment,
 438 non-mining tributaries largely dominated with a contribution of 80 % versus 6 % for mining
 439 tributaries. Along the Thio River, mining tributary contributions gradually increased to reach 70 %
 440 after the Mué tributary confluence (i.e. one of tributaries draining the Thio Plateau Mine, Figure 8-a,
 441 Table 4, sampling point [9]). The non-mining tributary contributions fluctuated along the Thio River
 442 between 41-85 % (Figure 8-a, Table 4, sampling points [2-8]) and reached a minimum (i.e. 28 %,
 443 Figure 8-a, Table 4, sampling point [9]) after the Mué tributary confluence. In the estuary, sediment
 444 supply was originated from 51-70 % of mining tributaries and 28- 52 % of non-mining tributaries
 445 (Figure 8-a, Table 4, sampling points [9, 10, 11]).

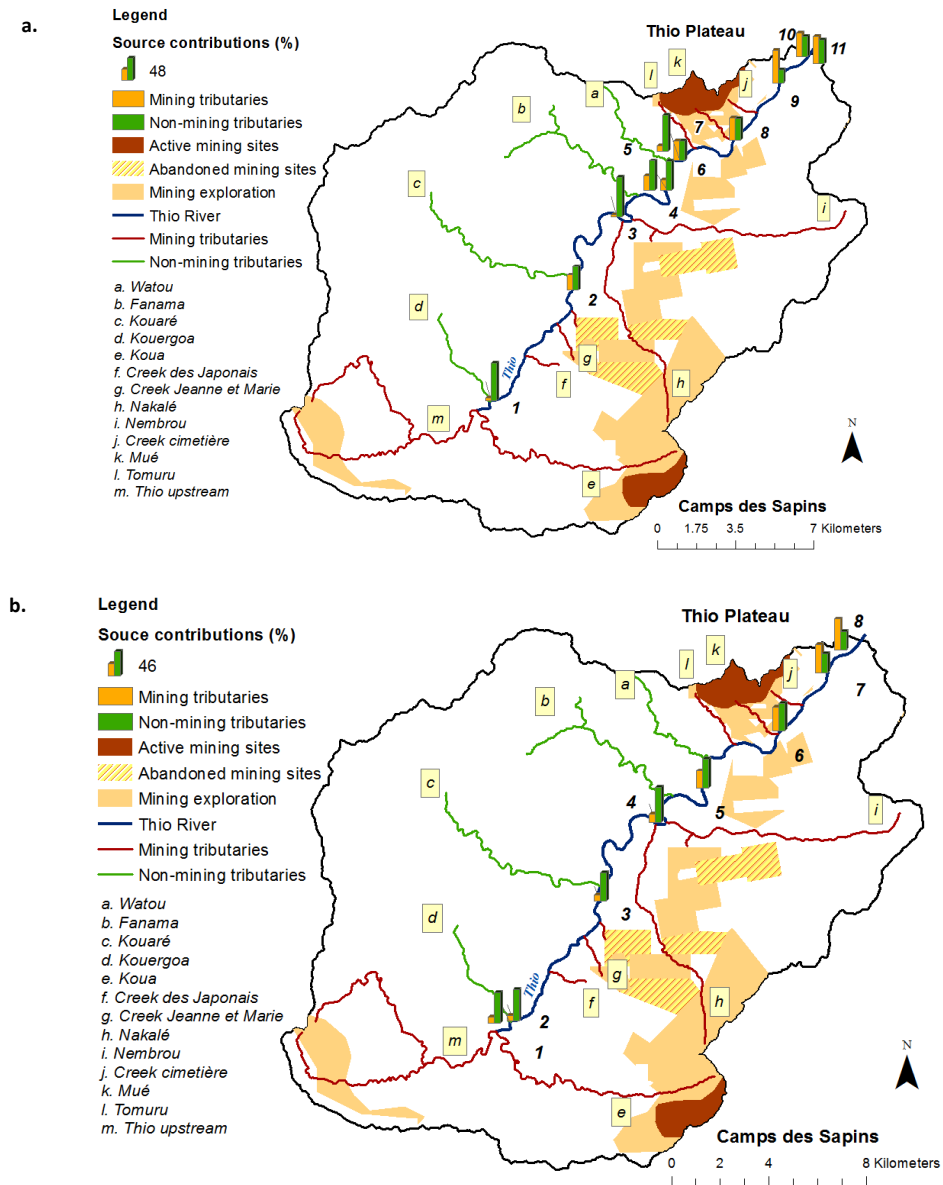

446 The FDVS-PLSR models also indicated that mining and non-mining tributaries respectively
 447 contributed a mean of 29 % (SD 20 %) and 51 % (SD 11 %) of sediment (Figure 8-b, Table 5) during
 448 the 2017 flood event. In a similar way, mining contributions gradually increased along the Thio River
 449 from 11 % in upper parts to reach 52-58 % in the estuary. On the contrary, non-mining contributions
 450 gradually decreased from 56 % in uppermost parts to reach 35-36 % in the estuary (Figure 8-b, Table
 451 5).

452 In summary, the FDVS-PLSR models provided opposite results to those of the conventional
 453 sediment fingerprinting approach (i.e. 'geochemistry' and 'colour + geochemistry' models). According

454 to the FDVS-PLSR models, non-mining tributaries contributed the majority of the sediment supply for
455 the 2015 (58 %, SD 18 %) and 2017 (51 %, SD 11 %) flood events. On the contrary, the 'geochemistry'
456 and 'colour + geochemistry' models demonstrated that mining tributary contributions dominated
457 sediment supply for the 2015 (i.e. respectively 65 % (SD 27%) and 68 % (SD 28 %)) and 2017 flood
458 events (i.e. respectively 83% (SD 8%) and 88 % (SD 8%)).

459

1.6.Complementary tests: representativeness of artificial mixture samples used for the FDVS-PLSR models compared to source samples

Given the opposite results obtained in terms of source contributions between FDVS-PLSR models on the one hand and 'geochemistry' and 'colour + geochemistry' models on the other hand, complementary analyses were carried out on individual source samples (i.e. not the composite samples used to create the artificial mixtures) to estimate their composition in terms of source contributions with FDVS-PLSR models. As done in Legout et al. (2013) to assess uncertainties in the fingerprinting approach due to source heterogeneity, they were considered as river sediment samples. A mean sum of the predicted source proportions of 94 % (SD 17 %, range: 49-131 %) was calculated from the source sample data set. The compositions of mining and non-mining tributary samples in Figures 9 and 10 show that artificial mixture samples built from a mix between the composite mining source sample and the composite non-mining source sample did not cover entirely the range of values found in all the sources samples, which may explain why some source samples showed mining and non-mining tributary composition lower than 0 and/or higher than 100 %.

Figure 9 Relative compositions of mining and non-mining sources estimated by the FDVS-PLSR models applied to the individual source sediment samples

Moreover, two sub-groups of mining tributary samples can be distinguished, the first one corresponding to samples collected on the mining tributaries located in the uppermost part of the catchment and the second to samples collected on the mining tributaries located further downstream. The FDVS-PLSR differentiated rather well the second group since the mining tributary composition is dominant in these samples. On the contrary, the first group referred to as 'Upstream' merged with the non-mining tributary samples (Figure 9). Indeed, Figure 10 shows the mining tributaries located in the upper part of the catchment were defined as 'non-mining tributaries' by the FDVS-PLSR model.

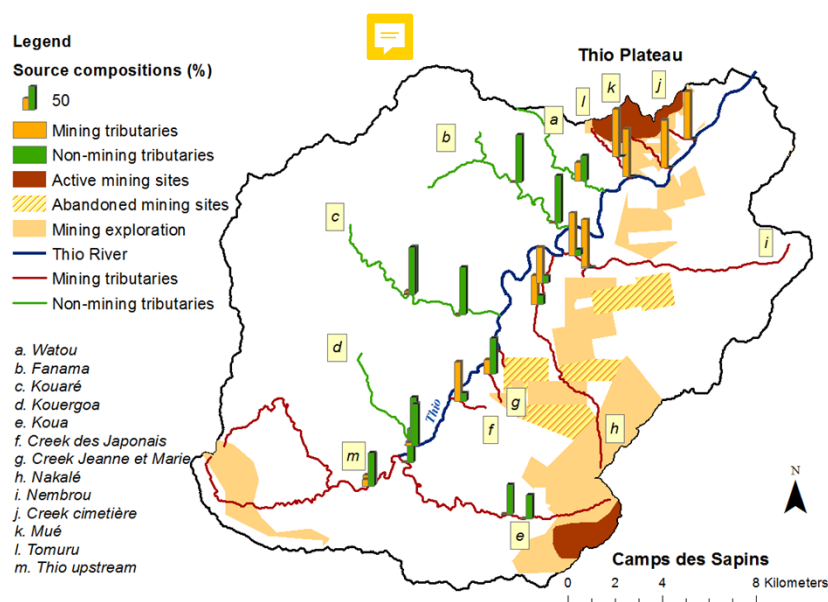

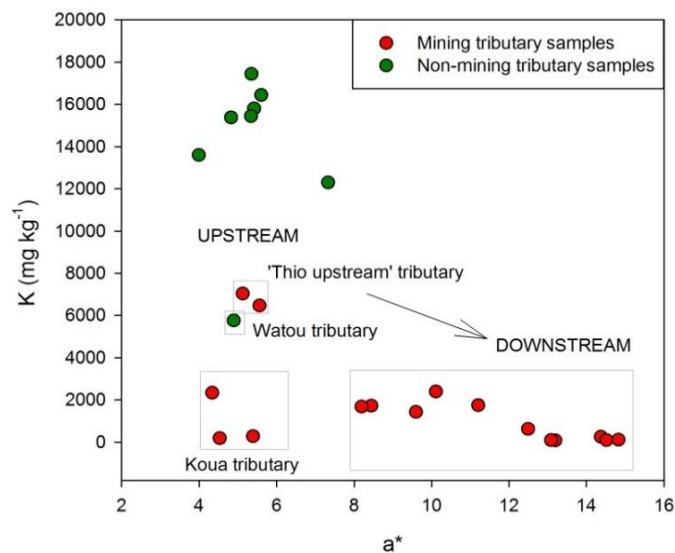

Figure 10 Relative compositions of mining and non-mining sources estimated by the FDVS-PLSR models applied to the individual sediment sources in the Thio River catchment

The low K contents found in these samples confirmed, however, that they were mainly supplied by mining sources (Figure 11). Nevertheless, a colour difference could be observed visually and through variations of the a^* parameter: the a^* values increased from upper parts to lower, which results in an increasingly red coloration of mining tributary samples in downstream direction. Figure 11 shows also that the a^* values found in samples collected in the upper catchment part

498 overlapped with those of non-mining tributary samples. Among the 'upstream' mining tributary
499 samples, only three samples collected on the Koua tributary (i.e. draining Camps des Sapins mine)
500 showed values that were not comprised in the ranges covered by the artificial mixture samples
501 (Figure 9).

502 **Figure 11** Diagram of K contents as a function of a^* parameter values within sediment sources and artificial
503 mixture samples

504 Discussion

505 1.7. Advantages and limits of models

506 1.7.1. 'Colour' model

507 One of the objectives of this study was to test the contribution of spectrophotometry for
508 improving the source discrimination. Indeed, visual observations indicated that mining tributary
509 samples were red-orange whereas non-mining tributary samples were rather grey. However, the
510 results showed that the colour parameters, when used individually, did not provide sufficient
511 discrimination between sources (Table 2) to meet this objective. Indeed, some mining tributary
512 samples showed colour parameter values similar to those found in non-mining tributary samples

513 (e.g. v' at Table 3, or a^* shown at Figure 11). This overlap of value ranges could explain in particular
514 the inability of the 'colour' model to provide satisfactory source discrimination. Nevertheless, results
515 obtained with colour parameter analyses coupled to visual observations highlighted the occurrence
516 of two groups of mining tributary samples (i.e. 'Upstream' and 'Downstream'). The coloration
517 differences (i.e. orange/ 'Upstream' and 'red/Downstream') observed between these two groups
518 could be due to the the fact that on the one hand, the reddish colour does not provide a highly
519 conservative signature as it may be altered by the oxydo-reduction of iron minerals during the
520 periods of submersion of sediments under water. On the other hand, the presence of different types
521 of nickel ores could explain these coloration differences. Indeed, nickel ore formation depends partly
522 on the morphological context, for instance on whether nickel ores are located in a basin, on a plateau
523 or a slope. This morphological context influences the weathering level of peridotites (i.e. laterite
524 profile: red laterites at the top >> yellow laterites >> saprolites >> peridotites at the bottom). In the
525 Thio River catchment, nickel ores from the Thio Plateau mine are 'plateau nickel ores' whereas those
526 from the Camps des Sapins mine are 'slope nickel ores' (Mardot et al., 2018). No information is
527 provided in the literature on the types of nickel ores that were mined in abandoned mining sites. The
528 red coloration of the 'Downstream' mining tributary samples could then be associated with more
529 altered laterite profiles with a thicker layer of red laterites compared to the 'Upstream' mining
530 tributary samples, which could be associated with a laterite profile with a thinner layer of red
531 laterites.

532 1.7.2. 'Geochemistry' model

533 The 'geochemistry' model based on K provided significant discrimination between sources
534 (Table 2), regardless of the types of nickel ores that may be found in the Thio River catchment. K is a
535 lithological tracer discriminating sediments originating from the erosion of the two dominant
536 lithologies (i.e. peridotite massifs vs. volcano-sedimentary formations) in the Thio River catchment.
537 As anthropogenic erosion (i.e. due to mining activities) dominates on the peridotite massifs (Garcin

et al., 2017), K therefore provides an optimal discrimination between mining and non-mining tributary contributions.

This parameter classified the source samples rather well (i.e. 95.3 % of correct classification, Table 3). Indeed, the 16 mining source samples were all correctly classified (100%) and only one non-mining source sample was not correctly classified (87.5 %), it corresponds to the Watou tributary sample (Figure 11). This sample showed a K content similar to that found in mining tributary samples. The Watou tributary is particular because it drains both volcano-sedimentary formations and peridotite massifs that were not exploited for mining, which justifies that it was considered as a non-mining tributary. The K content measured in this sample could be representative of that found in sediment sources characterized by a mix between the two dominant lithologies. Again, when observing Figure 11, two mining tributary samples (i.e. 'Thio upstream') showed similar K contents to that found in the Watou tributary sample. The 'Thio upstream' tributary also drains both areas associated with volcano-sedimentary formations and exploited peridotite massifs (i.e. mining prospection), which justifies that it was considered as a mining tributary.

The analysis of colour parameters coupled with that of geochemical elements indicated that these samples collected on the 'Thio upstream' tributary showed a less red coloration not because they are associated with a different type of ore, as could be the case for the samples collected on Koua tributary draining Camps des Sapins mine (Figure 11), but because they are characterized by a mix of both lithologies. As a result, the 'geochemistry' model showed a certain limitation to classify source samples characterized by a mix of both lithologies. The performance of the 'geochemistry' model described in Table 2 remains, however, excellent. The application of this model on artificial mixture samples provided very satisfactory results (Figure 3-a) with a good correlation between the predicted and the actual source proportions ($r^2 = 0.99$). An overestimation of mining tributary contributions is, however, to be taken into account. It was evaluated to a maximum at 15%. This

562 overestimation is greater when the mining contributions estimated by the model tend towards 0 %
 563 (maximum: 15.5 %, Figure 3-a).

564 1.7.3. 'Colour + geochemistry' model

565 The 'colour + geochemistry' (i.e. K, Ca, Ti, b*, C*) model provided the best discrimination
 566 between sources (Table 3). The inclusion of colour parameters in the 'colour + geochemistry'
 567 approach allowed for the discrimination of source samples (i.e. 100 % of correctly classified source
 568 samples) that a 'geochemistry' approach alone could not achieve. Results of the tests carried out on
 569 the artificial mixture samples also showed an excellent correlation between the predicted and the
 570 actual source proportions (i.e. $r^2 = 0.98$). A slight overestimation of the mining tributary contributions
 571 (7 %) was observed with this approach, which remains rather reasonable (Figure 3-b). In this model, K
 572 is the lithological tracer which has the higher discriminant powerful (Table 2), which may explain the
 573 similarity of results obtained with the 'colour + geochemistry' and the 'geochemistry' models.
 574 Indeed, mining tributaries contributed an average of 65 % (SD 27 %) for 'colour + geochemistry'
 575 model and 68 % (SD 25 %) for 'geochemistry' model (Table 4). For the 2017 flood event, mining
 576 source contributions largely dominated the sediment production with a mean contribution of 83 %
 577 (SD 8 %) for the 'geochemistry' model and 88 % (SD 8 %) for the 'colour + geochemistry' model.

578 1.7.4. FDVS-PLSR models

579 The FDVS-PLSR models built from artificial mixture samples showed excellent theoretical
 580 predictive performances (e.g. r^2 , RMSEC, RMSEC, Figure 5). However, the application of these models
 581 on river sediment samples provided questionable results. Indeed, the artificial mixture samples did
 582 not cover entirely the ranges of values found in all sources samples, thus resulting in an
 583 overestimation (i.e. superior to 100 %) and an underestimation (i.e. inferior to 0 %) of source
 584 composition (Figure 9) in several source samples. Similarly to what was previously observed, three
 585 sub-groups of mining tributary samples can be distinguished, one of which (i.e. 'Thio Upstream') is
 586 partially merged with the non-mining tributary samples (Figure 9). When modelling the source

contributions with the FDVS-PLSR models, a bias was created because the contributions of this mining tributary may be mainly considered as the contributions of non-mining tributaries. As a result, an overestimation of non-mining tributary contributions may be found in the entire Thio River catchment and particularly in the upper part of the study area. Third, the properties measured in the Koua tributary (i.e. draining Camps des Sapins Mine) samples were not comprised in the ranges of values covered by the artificial mixture samples (Figure 9).

Given the particular colour signature of this tributary (Figure 11), its contributions are therefore not taken into account at all by the FDVS-PLSR models. Indeed, the sums of the source contributions by FDVS-PLSR models are lower than the expected 100% particularly in the uppermost part of the catchment (Tables 4 and 5), which may indicate that a source is not accounted for. Artificial mixtures were constructed from a homogenized spectral signature of all mining source samples. However, two distinct spectral signatures were observed between the upstream and downstream mining source samples. Homogenizing the spectral signature of the mining samples led to a loss of information in terms of spectral signature, in particular that of the mining samples located upstream. As a result, a 3-source FDVS-PLSR models (i.e. non-mining, upstream and downstream mining sources) would have been more appropriate than 2-source FDVS-PLSR models in this context.

1.8. Spatial and temporal variations of sediment source contributions

Among the four models tested in this study, the 'colour + geochemistry' model is the most appropriate to estimate mining and non-mining tributary contributions in the Thio River catchment. According to the results of this model, mining tributaries provided the main sediment supply to the river system with a mean contribution of 68 % (SD 25 %) for the 2015 flood event and 88 % (SD 8 %) for the 2017 flood event (Tables 4 and 5). The variability of mining tributary contributions between these two flood events with a return period of 10 years ($3500 \text{ m}^3 \text{ s}^{-1}$) could be explained in particular by the variability of rainfall distribution (Sellier et al., 2019). Indeed, during the 2015 flood event, the

612 Kouaré River sub-catchment received twice the rainfall than observed in the rest of the Thio River
613 catchment, which may explain a higher contribution of non-mining tributaries for this event than for
614 the 2017 flood event where rainfall was more intense on the eastern part of the catchment in the
615 vicinity of the mines currently in operation (Thio Plateau, Camps des Sapins).

616 Although the FDVS-PLSR models were unable to properly estimate the source contributions,
617 they provided qualitative indications about the proportion of sediment contribution between
618 'Upstream' and 'Downstream' mining tributaries at the level of the estuary. Indeed, only
619 'downstream' mining tributaries were finally identified by the FDVS-PLSR models as mining sources.
620 Mining contributions gradually increased in downstream direction. The predicted proportion sums of
621 river sediment samples also tend to reach the expected 100%, which could result in a better
622 predictability of the models. As a result, these models indicated that sediment contribution from
623 downstream reaches dominated that of upstream reaches at the level of the estuary for both events.

624 Moreover, the analysis of colour parameters coupled to that of geochemical elements
625 highlighted the occurrence of three sub-groups of mining tributary samples, (1) 'Downstream'
626 samples characterized by high a^* values and low K contents, (2) 'Koua tributary' samples located in
627 the upstream characterized by low a^* values and low K contents and (3) 'Thio upstream' samples
628 corresponding to a mix of both dominant lithologies (i.e. peridotite massifs and volcano-sedimentary
629 formations) characterized by low a^* values and higher K contents (i.e. 4 times higher than for the
630 two previous sub-groups) (Figure 11). Owing to the low K contents found in Thio River sediment
631 samples collected in the uppermost part (i.e. $\sim 2200 \text{ mg kg}^{-1}$ in 2015 and $\sim 2600 \text{ mg kg}^{-1}$ in 2017),
632 which were similar to those measured in samples of sub-group (2, $\sim 2400 \text{ mg kg}^{-1}$), it would appear
633 that the Koua tributary draining Camps des Sapins mine dominated the sediment supply in the
634 upstream for both events.

635 Conclusions

636 The current study showed that the contributions of mining sources dominated the sediment
637 inputs with mean contributions of 68 % (SD 25 %) for the 2015 flood event and 88 % (SD 8 %) for the
638 2017 flood event (results of 'colour + geochemistry' model). Although the spatial variability of rainfall
639 may impact local sediment source contributions, a trend in terms of sediment source contributions is
640 observed along the Thio River for both flood events. In the uppermost part of the catchment, mining
641 source contributions dominated (99% in 2015, 100% in 2017) with a dominant contribution from the
642 Koua tributary draining the Camps des Sapins mine. The first non-mining tributary encountered in
643 downstream direction (i.e. the Kouergoa tributary) contributed little to sediment supply; it is rather
644 the next non-mining tributaries (i.e. the Kouaré tributary) which provided most of the sediment
645 inputs (83 % in 2015, 26 % in 2017). Nevertheless, these contributions were compensated in
646 downstream direction by those from mining sources generated by tributaries draining Thio Plateau
647 mine. Finally, at the estuary, mining sources dominated (58-70% in 2015, 83-85 % in 2017). These
648 results therefore suggest that catchment management should focus on mining tributaries draining
649 active mining sites (i.e. Camps des Sapins and the Thio Plateau).

650 One of the objectives of this study was to evaluate the performance of sediment tracing
651 methods based on spectroscopy measurements (i.e. colour parameters and FDVS). The results
652 showed that these individual fingerprinting approaches did not provide sufficient discrimination
653 between sources to be used for the modelling of sediment source contributions. Nevertheless, the
654 inclusion of colour properties in addition to geochemical parameters turned out to be the optimal
655 combination of tracers providing the highest discrimination between sediment sources. This 'colour +
656 geochemistry' model is, however largely based on the discriminatory power provided by K, which
657 means that the 'geochemistry' approach is also relevant to quantify sediment sources. Both
658 approaches have, moreover, been experimentally validated. As a result, the use of these approaches
659 could be extended to other mining catchments of New Caledonia but also to other similar nickel

660 mining catchments (i.e. Ni oxidized ores based on peridotite massifs) around the world (e.g.
661 Australia, Brazil, Dominican Republic, Cuba).

662 **Data availability**

663 The database has been registered on the PANGAEA website and is currently undergoing the editorial
664 process: <https://issues.pangaea.de/browse/PDI-25229>.

665 **Author contribution**

666 Oldrich Navratil, Michel Allenbach and Olivier Evrard designed research. Virginie Sellier, Oldrich
667 Navratil, Olivier Evrard and Irène Lefèvre carried out fieldwork sampling. Virginie Sellier conducted the
668 analyses. All co-authors contributed to data analysis and interpretation. John Patrick Laceby
669 contributed to modelling. All co-authors contributed to the writing and approved the final version of
670 the manuscript.

671 **Competing interests**

672 The authors declare that they have no conflict interest.

673 **Acknowledgements**

674 This work was funded by the National Technical Research Center (CNRT) “Nickel and Its
675 Environment”, Noumea, New Caledonia » (n°10PS2013-CNRT.UNC/IMMILA). The PhD project of
676 Virginie Sellier is also financed by the French Atomic Energy Commission (CEA, Commissariat à
677 l’Energie Atomique et aux Energies Alternatives). The authors are grateful to Jean-Guy M’Boueri,
678 Pierre Chanel, Jean-Jean, Lorenza M’Boueri, Nicole Mathys for their invaluable support to identify
679 and have access to the field sampling sites.
