26 **Abstract**

27 Aggregation affects a wide range of physical and biogeochemical soil properties with positive effects on
28 soil carbon storage. For weathered tropical soils, aluminous clays (kaolinite and gibbsite) and pedogenic
29 Fe (oxyhydr)oxides (goethite and hematite; termed 'Fe oxides') have been suggested as important building
30 units for aggregates. However, as aluminosilicates, aluminum hydroxides, and Fe oxides are part of the
31 clay-sized fraction it is hard to separate, how certain mineral phases modulate aggregation. In addition, it
32 is not known what consequences this will have for organic carbon (OC) persistence after land-use change.
33 We selected topsoils with unique mineralogical compositions in the East Usambara Mountains of
34 Tanzania under forest and cropland land uses, varying in contents of aluminous clay and Fe oxides.
35 Across the mineralogical combinations, we determined the aggregate size distribution, aggregate stability,
36 OC contents of aggregate size fractions as well as changes in aggregation and OC contents under forest
37 and cropland land use. Patterns in soil aggregation were rather similar across the different mineralogical
38 combinations (high level of macroaggregation and high aggregate stability). Nevertheless, we found some
39 statistically significant effects of aluminous clay and pedogenic Fe oxides on aggregation and OC storage.
40 An aluminous clay content $> 250 \text{ g kg}^{-1}$ in combination with pedogenic Fe contents $< 60 \text{ g kg}^{-1}$
41 significantly promoted the formation of large macroaggregates $> 4 \text{ mm}$. In contrast, a pedogenic Fe
42 content $> 60 \text{ g kg}^{-1}$ in combination with aluminous clay content of $< 250 \text{ g kg}^{-1}$ promoted OC storage and
43 persistence even under agricultural use. The combination with low aluminous clay and high pedogenic Fe
44 contents displayed the highest OC persistence, despite conversion of forest to cropland caused substantial
45 disaggregation. Our data indicate that aggregation in these tropical soils is modulated by the mineralogical
46 regime, causing moderate but significant differences in aggregate size distribution. Nevertheless,
47 aggregation was little decisive for overall OC persistence in these highly weathered soils, where OC
48 storage is more regulated by direct mineral-organic interactions.

49

50 **1. Introduction**

51 Many functions of soils such as food production, water purification as well as climate regulation are
52 tightly linked to soil structure (*Bronick and Lal, 2005; FAO, 2015; Six et al., 2004*). Aggregates are the
53 structural backbone of soil and changes in aggregation impacts various processes such as root
54 development, soil erosion, and soil organic carbon (OC) accumulation (*Chaplot et al., 2010; Le Bissonnais*
55 *et al., 2018*). Based on their size, soil aggregates are typically classified into small microaggregates
56 ($< 20 \mu\text{m}$), large microaggregates ($20\text{--}250 \mu\text{m}$), and macroaggregates ($> 0.25 \text{ mm}$) (*Tisdall and Oades,*
57 *1982*). Cementing agents such as clay minerals, metal (oxyhydr)oxides, as well as organic matter (OM)
58 are considered as primary building units of microaggregates (*Totsche et al., 2018*), which provide the basis
59 for the formation of larger soil structural units (*Asano and Wagai, 2014*). The study by *Six et al. (2002)*
60 points to the special role of inorganic compounds such as clay minerals and pedogenic metal oxides in the
61 formation of aggregates in the tropics. Pedogenic iron (Fe_d) (oxyhydr)oxides (summarized as ‘Fe oxides’)
62 have been reported to facilitate macroaggregation (*Peng et al., 2015*) and aggregate stability (*Duiker et al.,*
63 *2003*). Under the acidic conditions of weathered tropical soils, Fe oxides provide positively charged
64 surfaces capable of reacting with negatively charged inorganic constituents, like clay minerals or OM
65 (*Kaiser and Guggenberger, 2003; Kleber et al., 2015; Six et al., 2004; Totsche et al., 2018*). Aggregation
66 might be ascribed to inorganic or organic cementing agents with no consensus about the relevance of each
67 individual agent. Understanding the effects of individual cementing agents for aggregation is needed to
68 disentangle their potential contribution to soil aggregation. For example, the extent of aggregation has
69 been either positively related to the contents of clay and OC (*Chaplot and Cooper, 2015; Paul et al., 2008;*
70 *Spaccini et al., 2001*), or to differences in the clay mineral composition (*Fernández-Ugalde et al., 2013*).
71 Furthermore, *Barthès et al. (2008)* showed that texture had no effect on macroaggregation over a range of
72 tropical soils characterized by low-activity clay minerals. Uncertainty also derives from the fact that the
73 clay size particle fraction ($< 2\text{-}\mu\text{m}$) not only contains OM and different types of clay minerals, but also
74 variable contents of pedogenic Fe and aluminum (Al) oxides (*Barré et al. 2014; Fernández-Ugalde et al.*
75 *2013; Wagai and Mayer 2007*). *Denef et al. (2004)* showed that significant differences in the amount of

76 microaggregates encased in macroaggregates can be related to the clay mineral composition (2:1, mixed
77 layer, 1:1 clays). They assume that interactions of 1:1 clay minerals with Fe oxides cause a higher
78 aggregate stability compared to those involving 2:1 clay minerals (*Denef et al., 2002, 2004*). Such mutual
79 interactions between typical aluminous clay-sized minerals (e.g. kaolinite, gibbsite) and pedogenic Fe
80 oxides are thus possible drivers of aggregation in weathered tropical soils (*Durn et al., 2019*).

81 As indicated above, soil aggregation is considered to be an important process that increases OC
82 persistence, because of the physical separation of OM from microorganisms and their exoenzymes (*Six et*
83 *al., 2004*). Thus, improved aggregation could contribute to enhanced OC storage in soils (*Kravchenko et*
84 *al., 2015; Marín-Spiotta et al., 2008; Schmidt et al., 2011*). Managing aggregation, *e.g.*, for climate change
85 mitigation, requires profound knowledge on the controls of aggregation and their effects on OC
86 persistence (*Paul et al., 2008*). To the best of our knowledge there are no studies available, which
87 investigated the influence of changes in the content of clay minerals with low activity and the content of
88 pedogenic metal oxides on aggregation under comparable mineralogical conditions for weathered tropical
89 soils. Macroaggregates are particularly susceptible to soil management (*Six et al., 2000a; Totsche et al.,*
90 *2018*). Consequently, destruction of macroaggregates upon changes from forests to cropland might
91 account for OC losses that were observed in tropical soils (*Don et al., 2011; Kirsten et al., 2019; Mujuru et*
92 *al., 2013*). The stability of aggregates should thus determine OC losses induced by land-use change and
93 higher losses should be related to lower aggregate stability (*Denef et al., 2002; Le Bissonnais et al., 2018;*
94 *Six et al., 2000b*). We are currently not aware of any studies that solve the puzzle to which extent the
95 amount of aluminous clay and pedogenic Fe oxides controls soil aggregation and OC storage in highly
96 weathered soils of the humid tropics.

97 This study takes advantage of soils under natural forest and cropland in the East Usambara
98 Mountains of Tanzania. The mineralogical composition of the study soils is very homogeneous with
99 kaolinite and gibbsite as the main aluminous minerals of the clay fraction and goethite and hematite as
100 dominant pedogenic Fe oxides (*Kirsten et al., 2021*). Yet, the ratio of aluminous clays to Fe oxides
101 differed strongly, giving rise to unique mineralogical combinations under both land use types. Thus, the

102 conversion of natural forest to cropland in the study region enables us to evaluate the effect of land-use
103 change under each mineralogical combination on soil physical properties and related OC persistence. In
104 the precursor study, we found a positive relationship between the storage of mineral-associated OC and
105 the ratio of pedogenic Fe to aluminous clay under forest and cropland land use, suggesting that a larger
106 share of Fe oxides is linked to larger OC storage and persistency against land-use change (*Kirsten et al.*,
107 2021). In the present study, we test whether aggregation and its contribution to OC storage follow similar
108 patterns, or are decoupled from the individual contribution main mineral constituents. In detail, our main
109 research goal was to investigate the individual role of aluminous clay and pedogenic Fe oxides for
110 determining (i) the soil aggregate size distribution, (ii) aggregate stability, (iii) the consequences for OC
111 allocation into different aggregate size fractions, and (iv) the consequences for OC persistence related to
112 land-use change. We hypothesize that the mineralogical combination resulting in the largest aggregate
113 stability also results in the largest OC persistence. For this purpose, we determined the aggregate size
114 distribution of soils under both land uses, determined the OC contents of obtained aggregate fractions, and
115 tested the stability of the two largest aggregate size fractions (2–4 mm and > 4 mm). As a measure of OC
116 persistence, the OC content of aggregate size fractions was compared between the two land uses in the
117 same mineralogical combination. We generally focused on soil samples from 0–10 cm to test our current
118 hypothesis since land-use induced OC losses from soils of the study region largely occur in this depth
119 increment (*Kirsten et al.*, 2019).

120 **2. Material and methods**

121 **2.1 Study area and soil sampling**

122 The study was conducted in the Eastern Usambara Mountains of Tanzania close to the village Amani
123 (5°06'00" S; 38°38'00" E). The climate is humid monsoonal with a mean annual precipitation of
124 1,918 mm, and a mean annual temperature of 20.6°C with low variability within the study area (*Hamilton*
125 and *Bensted-Smith*, 1989). The dominating Acrisols and Alisols, developed from Precambrian crystalline
126 bedrock, are deeply weathered and highly leached, with visible clay illuviation in the subsoil (*Kirsten et*
127 *al.*, 2019). Briefly, all soil samples were collected on mid-slope position. We sampled six plots under
128 forest and three under annual cropping. The site selection was done based on total clay amount determined
129 in the field and the associated total Fe amount measured with a portable XRF device (*Kirsten et al.*, 2021).
130 We did not observe systematic differences in vegetation composition of the forest sites and NMR spectra
131 showed a similar composition of litter for each of the two land uses investigated (*Kirsten et al.*, 2021) .
132 Furthermore, several visits in the study region over the last decade (2012, 2013, 2015, and 2018)
133 combined with personal talks to farmers and local partners working in the region, enabled us to select
134 cropland sites with similar agricultural management (cultivation of cassava (*Manihot esculenta*), hand hoe
135 tillage, biomass burning before seed bed preparation). At each plot, mineral soil from three adjacent and
136 randomly distributed soil pits at mid-slope position was sampled at 0–5 and 5–10 cm depths. Living roots
137 were removed and aliquots of the soils were sieved to < 2 mm after drying at 40°C. For each depth
138 increment, three undisturbed soil cores (100 cm³) were collected for bulk density determination.

139

140 **2.2 Soil analyses**

141 *Basic soil properties and selected mineralogical combinations*

142 Bulk density was determined after drying the soil at 105°C and corrected for coarse fragments (*Carter and*
143 *Gregorich*, 2008). Soil pH was measured in 0.01 M CaCl₂ at a soil to solution ratio of 1 : 2.5. Extraction
144 of poorly crystalline Fe and Al phases as well as of Fe and Al complexed by OM was done with
145 ammonium oxalate according to *Schwertmann* (1964). Effective cation exchange capacity (CEC_{eff}) and

146 base saturation (BS) were determined following the procedure provided by *Trüby and Aldinger (1989)*.
147 Contents of OC and total N were analyzed by high temperature combustion at 950°C and thermo-
148 conductivity detection (Vario EL III/Elementar, Heraeus, Langenselbold, Germany). A combined
149 dithionite-citrate-bicarbonate extraction and subsequent texture analysis was applied to determine the
150 contents of aluminous clay and total pedogenic Fe (Fe_d). Briefly, 5–6 g soil pre-treated with 30% H_2O_2
151 were extracted with 30 g sodium dithionite ($Na_2S_2O_4$) and 1.35 L buffer solution (0.27 M trisodium citrate
152 dihydrate ($C_6H_5Na_3O_7 \cdot 2H_2O$) + 0.11 M sodium bicarbonate ($NaHCO_3$)) at 75°C in a water bath for
153 15 min (*Mehra and Jackson, 1958*). The Fe concentration of the extracts were measured by inductively
154 coupled plasma optical emission spectroscopy (ICP-OES) using a CIROS-CCD instrument (Spectro,
155 Kleve, Germany). The residues of the extraction were then subjected to a texture analysis using the pipette
156 method (*Gee and Bauder, 1986*). Details of the procedure are described in *Kirsten et al. (2021)*. Based on
157 the respective content of aluminous clay and pedogenic Fe oxide in the 5–10 cm depth increment, each
158 sample was assigned to a certain mineralogical combination. The threshold values for aluminous clay and
159 pedogenic Fe oxides to distinguish between “high” and “low” were set to 250 g kg^{-1} and 60 g kg^{-1} ,
160 respectively. We differentiated four groups varying in contents of aluminous clay and pedogenic Fe oxides
161 under forest (i.e. ‘low clay–low Fe’, ‘low clay–high Fe’, ‘high clay–low Fe’, ‘high clay–high Fe’), and
162 three analogous groups under cropland (i.e. ‘low clay–low Fe’, ‘low clay–high Fe’, ‘high clay–high Fe’).

163

164 *Aggregate size distribution, aggregate stability and carbon contents*

165 Aggregate size distribution was determined by dry sieving as it most closely resembles soil conditions at
166 the end of the long dry season. Undisturbed soil was dried at 40°C for 48 hours. Separation of aggregate
167 sizes was conducted with a sieving machine (AS 200 control “g”, Retsch, Hanau, Germany) combined
168 with a set of four sieves with meshes of 4, 2, 1, and 0.25 mm, respectively (*Larney, 2008*). The amplitude
169 was set to 1.51 mm (7.6 g-force), which was applied over a sieving duration of three minutes. Aggregate
170 stability was tested for the two largest aggregate size fractions (2–4 mm and > 4 mm). The fast wetting
171 pretreatment was applied to both fractions (*Le Bissonnais, 1996*) using a wet-sieving apparatus

172 (Eijkelkamp, Giesbeek, Netherlands) with sieve openings of 63 μm . This procedure simulates the
 173 transition of aggregates from dry to rainy season. Sieving was conducted in ethanol for three minutes
 174 (stroke 1.3 cm, $f = 34 \text{ min}^{-1}$). All aggregates remaining on the sieve were dried at 105°C. Water-stable
 175 aggregates were subsequently introduced to a sieving apparatus with a set of five sieves with mesh sizes of
 176 4, 2, 1, 0.63, and 0.25 mm, respectively (Larney, 2008). For each obtained aggregate fraction by dry
 177 sieving, OC contents analyzed by high temperature combustion at 950°C and thermo-conductivity
 178 detection (Vario EL III/Elementar, Heraeus, Langensfeld, Germany). The mass corrected OC content of
 179 a certain aggregate fraction was calculated using equation 1 to resemble the contribution to total soil OC,

$$180 \text{ Mass - corrected } OC_{Aggregate} = \frac{m_i}{\sum_{i=0}^n m_i} \times OC_{Aggregate} \quad (\text{Eq. 1})$$

181 where m_i represents the mass of an aggregate size fraction (g), $\sum m_i$, the sum of masses of all size
 182 fractions (g), and $OC_{Aggregate}$ the OC content of aggregate fraction "i".

183 The mean weight diameter (MWD) of aggregates was calculated using equation 2 for undisturbed soil to
 184 describe the initial aggregate size distribution, and for the large aggregate size fractions after exposure to
 185 the stability test to evaluate the effect of fast wetting on aggregate stability,

$$186 MWD = \sum_{i=0}^n \frac{m_i}{\sum m_i} \times d_i \quad (\text{Eq. 2})$$

187 where m_i represents the mass of an aggregate size fraction (g), $\sum m_i$, the sum of masses of all size
 188 fractions (g), and d_i the mean mesh diameter of fraction "i" (mm). The MWD of the aggregate fraction
 189 > 4 mm was estimated by doubling the largest sieve size diameter (Youker and McGuinness, 1957).

190

191 **2.3 Statistics and calculations**

192 The mean and standard deviation of data were calculated with the software package R (version 3.6.0). To
 193 test for significant differences between treatments, linear model function [lm()] was used in combination
 194 with analysis of variance [aov(lm())]. The Tukey-HSD test was used as a post-hoc comparison of means;
 195 the LSD-test was applied in the case of non-equality of variances. Regression analysis was used to test for
 196 relationships between mineralogical properties and MWD, masses of aggregate size fractions, aggregate
 197 stability, and OC losses due to land-use change. Statistical differences are reported at a significance level

198 of $p < 0.05$. Based on our selected threshold values for aluminous clay and pedogenic Fe oxides, we were
199 able to achieve the following number of replicates for the mineralogical combinations: 'low clay–low Fe'
200 under forest ($n = 4$), 'low clay–high Fe' under forest ($n = 4$), 'high clay–low Fe' under forest ($n = 3$), 'high
201 clay–high Fe' under forest ($n = 7$); all cropland combinations ($n = 3$).

202

203 **3. Results**

204 **3.1 Mineralogical composition and general soil properties**

205 The selected mineralogical combinations represent a broad spectrum of possible combinations mineral
206 aluminous clay and Fe oxide constituents. Amounts of aluminous clay varied between 149 and 438 g kg⁻¹,
207 and Fe_d between 21 and 101 g kg⁻¹ across all sites and land uses. Amorphous Fe and Al phases
208 contributed little to pedogenic oxides as indicated by low proportions of oxalate-extractable Fe and Al
209 (Table 1). The advanced weathering state of study soils was also reflected in low pH and CEC_{eff} values
210 (Table 1).

211 **Table 1:** Basic properties of the two soil depth increments sampled along the mineralogical combinations with aluminous clay
 212 (clay), dithionite-citrate-bicarbonate-extractable Fe (Fe_d), total soil organic carbon content (OC), Fe_d to aluminous clay ratios
 213 ($Fe_d/clay$), effective cation exchange capacity (CEC_{eff}), hydrogen peroxide- and dithionite-citrate-bicarbonate-treated sand and
 214 silt contents, and oxalate-extractable Fe and Al content (Fe_o and Al_o). Aluminous clay represents the weight sum of kaolinite and
 215 gibbsite present in the $< 2\text{-}\mu\text{m}$ fraction after removal of OM and pedogenic Fe oxides. Lower case letters indicate significant
 216 differences within a certain land use as separated by depth. Sample numbers for the combinations are as follows: ‘low clay–low
 217 Fe’ under forest ($n = 4$), ‘low clay–high Fe’ under forest ($n = 4$), ‘high clay–low Fe’ under forest ($n = 3$), ‘high clay–high Fe’
 218 under forest ($n = 7$); all cropland combinations ($n = 3$).

219 3.2 Aggregate size distribution

220 The studied soils were highly aggregated and showed significant variation in their aggregate size
221 distribution across the mineralogical combinations (Table 2). For most combinations, about 74% of soil
222 mass was present in aggregates > 2 mm (Figure 1a), whereas in forest soils with low contents in both
223 aluminous clay and Fe oxides only 40% could be assigned to aggregates > 2 mm. Only 3–12% of total soil
224 mass remained in < 0.25 mm aggregates (Table 2). The low clay–low Fe combination under forest
225 displayed the significant smallest MWD, with 2.9 mm in 0–5 cm depth and 3.7 mm in 5–10 cm depth
226 (Table 2). In contrast, the low clay–high Fe combination always had the largest MWD (4.8 mm in 0–5 cm
227 depth, and 4.6 mm in 5–10 cm depth) among the other forest combinations. Our data suggest that the
228 MWD under forest is significantly positively influenced by the Fe_d content ($MWD_{Forest\ 0-5\ cm}: r^2 = 0.4,$
229 $p < 0.001$; $MWD_{Forest\ 5-10\ cm}: r^2 = 0.15, p = 0.06$), whereas nearly no effect was observed for aluminous clay
230 ($MWD_{Forest\ 0-5\ cm}: r^2 < 0.01, p = 0.79$; $MWD_{Forest\ 5-10\ cm}: r^2 < 0.01, p = 0.30$, Table S1). Contrary to the
231 mineralogical combinations under forest, the significant smallest MWD under cropland was within the
232 low clay–high Fe combination (2.7 mm in 0–5 cm depth and 2.7 mm in 5–10 cm depth; Table 2). The low
233 clay–low Fe and high clay–high Fe cropland combinations showed no strong differences in their MWDs.
234 Nonetheless, a significant negative linear relationship existed between MWD and the pedogenic-Fe to
235 aluminous clay ratio ($MWD_{Cropland\ 0-5\ cm}: r^2 = 0.47, p = 0.03$; $MWD_{Forest\ 5-10\ cm}: r^2 = 0.47, p = 0.02$) for the
236 mineralogical combinations under cropland (Table S1).

237 Corresponding to the smallest MWD, the low clay–low Fe forest combination contained the
238 smallest fraction of > 4 mm aggregates. The contribution of these large aggregates under forest increased
239 in the order: low clay–low Fe < low clay–high Fe = high clay–high Fe < high clay–low Fe (Figure 1a). For
240 croplands, the low clay–high Fe combination comprised the smallest amount of > 4 mm aggregates
241 whereas the high clay–high Fe combination exhibited the respective highest share (Figure 1a). The
242 explained variance of > 4 mm aggregate mass due to aluminous clay and Fe_d was generally low, except for
243 the cropland combinations (positive effect of aluminous clay and negative effect of pedogenic Fe; Table
244 S1).

245 **Figure 1:** Aggregate size distribution of the combined 0–5 and 5–10 cm depth increments (a), and relative
 246 mass-corrected OC contents (b) along the mineralogical combinations. Clay represents the weight sum of
 247 kaolinite and gibbsite present in the < 2- μ m fraction after removal of OM and pedogenic Fe oxides, and
 248 Fe denotes the content of pedogenic Fe oxides extracted with dithionite-citrate-bicarbonate. Sample
 249 numbers for the combinations are as follows: ‘low clay–low Fe’ under forest ($n = 4$), ‘low clay–high Fe’
 250 under forest ($n = 4$), ‘high clay–low Fe’ under forest ($n = 3$), ‘high clay–high Fe’ under forest ($n = 7$); all
 251 cropland combinations ($n = 3$).
 252
 253

254 The mineralogical combinations affected the amounts of 2–4 mm aggregates differently than those
 255 of > 4 mm aggregates. The low clay–high Fe combination under forest and cropland contained slightly but
 256 significantly more 2–4 mm aggregates (Figure 1a), being associated with a significantly higher Fe_d to
 257 aluminous clay ratio (Table 1). In fact, in a multiple regression model for the entire data set (combined
 258 land uses and depths), we observed a positive relationship between the mass of 2–4 mm aggregates and
 259 Fe_d content, whereas the content of aluminous clay had a negative effect ($r^2 = 0.57$, $p < 0.001$; Table S1).
 260 The same model separated by soil depth showed similar relationships (Table S1). Across all mineralogical
 261 combinations, amounts of < 0.25 mm aggregates were principally comparable, despite of significantly
 262 higher shares in the low clay–low Fe and high clay–high Fe combinations under forest. In contrast, a
 263 significant larger amount of < 0.25 mm aggregates was observed in the low clay–high Fe combination
 264 under cropland. In this mineralogical combination, land-use change caused a quadrupling of < 0.25 mm
 265 aggregate mass from about 30 to nearly 120 g kg⁻¹ (Table 2). In contrast to the macroaggregate fractions

266 shown above, there was no correlation between mineralogical parameters and the mass of < 0.25 mm
267 aggregates, neither for the entire data set (combined land uses and depths) nor when separated by soil
268 depth (Table S1). Only under cropland we observed a negative effect of aluminous clay and a positive
269 influence of Fe_d on microaggregate contents (aggregate mass < 0.25 mm_{0-5 cm}: $r^2 = 0.8$, $p = 0.004$;
270 aggregate mass < 0.25 mm_{5-10 cm}: $r^2 = 0.61$, $p = 0.03$).

Table 2: Aggregate masses (mass) and OC content of aggregate size fractions (dry sieving) within different combinations of aluminous clay and pedogenic Fe oxides, OC change (Δ OC) between land uses within a certain mineralogical combination and depth, and related mean weight diameter (MWD). Aluminous clay represents the weight sum of kaolinite and gibbsite present in the $< 2\text{-}\mu\text{m}$ fraction after removal of OM and pedogenic Fe oxides. Lower case letters indicate significant differences within a certain land use separated by depth, and capital letters denote significant differences between land uses. Sample numbers for the combinations are as follows: 'low clay–low Fe' under forest ($n = 4$), 'low clay–high Fe' under forest ($n = 4$), 'high clay–low Fe' under forest ($n = 3$), 'high clay–high Fe' under forest ($n = 7$); all cropland combinations ($n = 3$).

278

279 In summary, mineralogical combinations and land use significantly affected the aggregate size
280 distribution of soils, despite quantitative relations to mineralogical proxies could not be observed for each
281 aggregate class. In undisturbed forest soils, higher pedogenic Fe contents resulted in increasing MWD
282 especially in 0–5 cm depth and significantly larger amounts of > 2 mm aggregates. The conversion from
283 forest to croplands either decreased MWD, as particularly observed for the low clay–high Fe combination,
284 or had no effect (low clay–low Fe). Overall, the observed differences in aggregate masses and MWD were
285 surprisingly moderate, given the widely differing contents in aluminous clay and Fe oxides across the
286 mineralogical combinations.

287

288 **3.3 Aggregate stability**

289 In general, there was little variation of MWD values for > 4 mm aggregates over all mineralogical
290 combinations. In fact, the MWD of this fraction was always close to its calculated mean diameter (6 mm;
291 calculation was done after (*Youker and McGuinness, 1957*)), overall indicating a high stability.
292 Nevertheless, there were some minor differences in aggregate stability across mineralogical combinations.
293 The low clay–low Fe and high clay–low Fe combinations had a significantly lower aggregate stability in
294 comparison with the two other combinations under the two land uses (Table 3). The slightly higher
295 abundance of 2–4 mm aggregates in the low clay–high Fe combination under forest and cropland was
296 accompanied by a significantly higher aggregate stability under both land uses (Table 2 and 3). In
297 summary, all aggregates can be classified as stable with only minor differences imposed by the
298 mineralogical combinations. Slightly higher aggregate stability was associated with a larger amount of
299 pedogenic Fe, and increasing Fe_d to aluminous clay ratios, whereas differences in the amount of aluminous
300 clay had almost no effect on the aggregate stability (Table S2).

301

302

303

304

305 **Table 3:** Aggregate stability of selected aggregate size fractions after applying the fast wetting procedure
 306 along the different combinations of aluminous clay and pedogenic Fe oxides, indicated by the resulting
 307 mean weight diameter (MWD). Aluminous clay represents the weight sum of kaolinite and gibbsite
 308 present in the < 2- μ m fraction after removal of OM and pedogenic Fe oxides. Lower case letters indicate
 309 significant differences within a certain land use separated by depth, and capital letters denote significant
 310 differences between land uses. Sample numbers for the combinations are as follows: 'low clay–low Fe'
 311 under forest ($n = 4$), 'low clay–high Fe' under forest ($n = 4$), 'high clay–low Fe' under forest ($n = 3$), 'high
 312 clay–high Fe' under forest ($n = 7$); all cropland combinations ($n = 3$).

Land use	Mineralogical combination	Depth (cm)	MWD	
			Fast wetting > 4 mm	Fast wetting 2–4 mm
			(mm)	(mm)
Forest	Low aluminous clay–	0–5	4.9 ^{b,A} (0.4)	2.6 ^{b,A} (0.1)
	Low pedogenic Fe oxides	5–10	5.1 ^{a,A} (0.3)	2.4 ^{b,A} (0.3)
Forest	Low aluminous clay–	0–5	5.6 ^{a,A} (0.2)	2.8 ^{a,A} (0.1)
	High pedogenic Fe oxides	5–10	4.9 ^{a,A} (0.9)	2.7 ^{a,A} (0.1)
Forest	High aluminous clay–	0–5	5.4 ^{ab} (0.4)	2.7 ^b (0.0)
	Low pedogenic Fe oxides	5–10	4.5 ^a (1.2)	2.4 ^b (0.3)
Forest	High aluminous clay–	0–5	5.5 ^{a,A} (0.2)	2.6 ^{b,A} (0.1)
	High pedogenic Fe oxides	5–10	5.2 ^{a,A} (0.4)	2.6 ^{ab,B} (0.1)
Cropland	Low aluminous clay–	0–5	4.4 ^{b,A} (0.1)	2.6 ^{c,A} (0.0)
	Low pedogenic Fe oxides	5–10	4.9 ^{b,A} (0.3)	2.4 ^{b,A} (0.1)
Cropland	Low aluminous clay–	0–5	5.2 ^{a,A} (0.2)	2.9 ^{a,A} (0.0)
	High pedogenic Fe oxides	5–10	5.3 ^{ab,A} (0.1)	2.8 ^{a,A} (0.0)
Cropland	High aluminous clay–	0–5	4.9 ^{a,B} (0.2)	2.7 ^{b,A} (0.1)
	High pedogenic Fe oxides	5–10	5.6 ^{a,A} (0.2)	2.8 ^{a,A} (0.0)

313

314 3.4 Organic carbon in soils and aggregate size fractions

315 Variation in mineral constituents caused different soil OC contents, ranging between 19 to 95 g OC kg⁻¹
 316 across all sites including both land use and depth (Table 1). A significant proportion of the total OC
 317 content of all forest soils was present in > 4 mm aggregates in both depth increments (low clay–low Fe:

318 33% < high clay–high Fe: 43% < high clay–low Fe: 51% < low clay–high Fe: 52%; Figure 1b). Forest to
 319 cropland conversion caused OC losses from most aggregate size fractions (Figure 2). For the > 4 mm
 320 aggregates this was significantly modified by the mineralogical combinations at least at 0–5 cm depth,
 321 generally following the order: low clay–high Fe < high clay–high Fe < low clay–low Fe (Table S3).
 322 Losses of OC from aggregate size fractions were generally higher at 0–5 than at 5–10 cm depth (Figure 2).
 323 As mentioned above, no significant loss of total OC occurred for the low clay–high Fe combination,
 324 irrespective of the significant mass redistribution of the > 4 mm aggregate fraction into smaller aggregate
 325 fractions (Table 2). Although there were differences in OC losses among mineralogical combinations,
 326 there was little indication that coarser aggregate size fractions lost more OC than smaller ones (Table 2).
 327

328 **Figure 2:** Mass-corrected OC contents of aggregate size fractions along the mineralogical combinations.
 329 Clay represents the weight sum of kaolinite and gibbsite present in the < 2- μ m fraction after removal of
 330 OM and pedogenic Fe oxides, and Fe denotes the content of pedogenic Fe oxides extracted with
 331 dithionite-citrate-bicarbonate. Sample numbers for the combinations are as follows: 'low clay–low Fe'
 332

333 under forest ($n = 4$), 'low clay–high Fe' under forest ($n = 4$), 'high clay–low Fe' under forest ($n = 3$), 'high
334 clay–high Fe' under forest ($n = 7$); all cropland combinations ($n = 3$).
335

336 **4. Discussion**

337 The aggregate size distribution of soils along the mineralogical combinations under both land uses were in
338 the range of values reported for African soils. For example, soils with strongly contrasting clay content
339 (220 and 650 g kg⁻¹) but similar clay mineralogy (kaolinite) in the central highlands of Kenya displayed
340 macroaggregate contents of 245 and 636 g kg⁻¹ soil, respectively (*Gentile et al., 2010*). In addition, for
341 soils from the catchment of the Riru river also located in the central highlands of Kenya it was shown that
342 macroaggregates (2–4.2 mm) displayed a large stability (*Kamamia et al., 2021*). The reported MWD's
343 after application of the fast-wetting stability test were 2.5 mm for cropland and 3.2 mm for indigenous
344 forest sites (*Kamamia et al., 2021*). These values are close to those observed in our study soils for 2–4 mm
345 aggregates. In contrast, soils in Brazil under native forest vegetation and similar mineral composition
346 (kaolinite, gibbsite, hematite) even subsumed over 90% of total aggregate mass in > 2 mm aggregates
347 (*Maltoni et al., 2017*). Nonetheless, reported data all point at a better soil structure and aggregate stability
348 of tropical soils dominated by low-activity clay minerals and well-crystalline Fe oxides, which is
349 consistent with all mineralogical combinations of this study.

350

351 **4.1 Aggregation and aggregate stability as controlled by aluminous clay and pedogenic Fe oxides**

352 Our data demonstrates relatively small differences in aggregation among the generally well-aggregated
353 study soils, being characterized by high aggregate stability despite of large variations in aluminous clay
354 (factor three) and pedogenic Fe (factor five) contents. Yet, we noticed some distinct modifications of the
355 aggregation size distribution and aggregate stability in both forest and cropland soils. The low clay–low
356 Fe soil under forest had a significantly smaller amount of > 4 mm and 2–4 mm aggregates and a
357 significantly lower MWD than all other mineralogical combinations. Notably, a combined increase in
358 aluminous clay and Fe oxides did not necessarily cause a shift towards larger aggregates and thus higher
359 MWD (see low clay–high Fe forest). Furthermore, the low clay–low Fe and high clay–high Fe
360 combinations under forest contained more < 0.25 mm aggregates. Thus, under undisturbed soil conditions
361 it appears that the formation of larger aggregates is promoted if one of the two aggregate-forming mineral

362 fractions is more abundant than the other (high clay–low Fe and low clay–high Fe combinations). We
363 assume that the positive effect of increasing aluminous clay content on the aggregate mass > 4 mm is
364 related to the hybrid electrostatic properties of kaolinite on edges (variable) and surfaces (permanent
365 negative), which enable the formation of characteristic cards-house structures (*Qafoku and Sumner, 2002*).
366 In addition to this increase in aggregation caused by the dominance in kaolinitic properties (i.e. high
367 clay–low Fe), we also expect that, similar to the study by *Dultz et al. (2019)*, there are mixing ratios
368 between aluminous clay and pedogenic Fe minerals, which lead to improved aggregation (greater MWD;
369 i.e. low clay–high Fe). This effect is probably explained by changes in the electrostatic properties of the
370 mineralogical combinations, as was shown in the study by *Hou et al. (2007)* for kaolinite in different
371 relative combinations with goethite and hematite. Nevertheless, aluminous clay is the decisive control for
372 macroaggregation in these weathered tropical soils, confirming the often described promoting effect of
373 increasing clay content on aggregation (*Feller and Beare, 1997*). Furthermore, the high clay–low Fe and
374 high clay–high Fe combinations under forest also nicely demonstrate how nearly equal amounts of
375 aluminous clay plus pedogenic Fe oxides (i.e. similar clay contents) cause different amounts of > 4 mm
376 aggregates. Consequently, the connection between textural properties and aggregation can remain hidden
377 (*Barthès et al., 2008*) without considering the mineralogical composition of the whole clay fraction
378 (*Fernández-Ugalde et al., 2013; King et al., 2019; West et al., 2004*).

379 Land-use change had a distinct impact on aggregate distribution like indicated in other studies
380 (*Feller and Beare, 1997; Six et al., 2002*) and depended also on the mineralogical combinations, though
381 croplands not followed the trajectory observed under forest. A significantly lower MWD under low
382 clay–high Fe rather than low clay–low Fe can be mainly attributed to a reduced amount of > 4 mm
383 aggregates. We assume that differences in the ratio of pedogenic Fe to aluminous clay in the low clay–low
384 Fe and high clay–high Fe (0.13 to 0.15) in comparison with the low clay–high Fe combination (0.47 to
385 0.51) under cropland explains the stability of ‘card-house’ structures like described for mineralogically
386 similar Oxisols from Brazil and India (*Bartoli et al., 1992*). Accordingly, a higher Fe_d to aluminous clay
387 ratios seems to be disadvantageous for the formation of such structures, especially in > 4 mm aggregates.

388 The different pH-dependent charge characteristics of kaolinite and pedogenic Fe oxides (*Kaiser and*
389 *Guggenberger, 2003*), and their relative share can lead to altered charge properties of soils (*Anda et al.,*
390 *2008*). We hypothesize, that an increasing amount of Fe oxides in the investigated mineralogical
391 combinations adds more positive charge, thus possibly reducing structural integrity and aggregate stability
392 if not sufficiently compensated by OM or clay minerals. Furthermore, in the low clay–high Fe cropland
393 combination, land-use change caused a significant four-fold increase of < 0.25 mm aggregates due to the
394 breakdown of > 4 mm aggregates. Nonetheless, our results show that agricultural management does not
395 necessarily decrease macroaggregation and related MWD's, like reported in *Rabbi et al. (2015)*.

396 The dominant role of pedogenic Fe oxides for macroaggregation under undisturbed tropical soil
397 conditions proposed by *Six et al. (2002)* cannot be confirmed in our study. This is because the low
398 clay–high Fe forest soil contained a smaller amount of > 4 mm aggregates compared to the high clay–low
399 Fe forest soil in both depth increments. Consequently, this rather points at the importance of kaolinite for
400 macroaggregation, which is in line with results from two Oxisols in Brazil (*Vrdoljak and Sposito, 2002*),
401 showing kaolinite being the backbone of the investigated aggregate size fractions. The less intense
402 formation of > 4 mm aggregates in the low clay–high Fe forest combination was also observed under
403 cropland, whereas the low clay–low Fe and high clay–high Fe croplands showed either no significant
404 decrease or even an increase in > 4 mm aggregate mass. Thus, simultaneous abundance of large amounts
405 of aluminous clay and pedogenic Fe oxides preserved a higher aggregate stability than under
406 mineralogically imbalanced conditions, although no conclusions can be drawn for the high clay–low Fe
407 combination. Nonetheless, > 4 mm aggregates had a higher resistance to field operations in mineralogical
408 combinations with lower Fe_d to aluminous clay ratios (0.13 to 0.15).

409 In contrast to the > 4 mm aggregates, 2–4 mm aggregates corresponded more clearly to the positive
410 effect of pedogenic Fe oxides on aggregation and aggregate stability as proposed for weathered tropical
411 soils (*Igwe et al., 2013; Peng et al., 2015; Six et al., 2002*). Both, the low clay–high Fe forest and low
412 clay–high Fe cropland soils contained somewhat but significantly more 2–4 mm aggregates than other
413 mineral combinations in concert with a higher aggregate stability of this particular fraction. This finding

414 also demonstrates that mineral interactions forming water-stable aggregates in tropical soils are differently
415 affected by a given mineralogical combination. Higher Fe_d to aluminous clay ratios (> 0.45) modulate
416 aggregate distribution towards aggregates 2–4 mm, whereas distinctly lower values (high clay–low Fe
417 forest: 0.12) shifted the maximum to > 4 mm aggregates. Overall, the two macroaggregate fractions
418 discussed above are differentially affected by the mineralogical combinations, although the magnitude was
419 less than expected, given the pronounced variation in aluminous clay and Fe contents.

420 421 **4.2 Importance of aggregation for OC persistence – effects of aluminous clay and pedogenic Fe ox-** 422 **ides**

423 Clay minerals and Fe oxides are considered as important mineral constituents fostering aggregation and
424 subsequent OC storage via physical protection (*Denef et al., 2004*). The overwhelming portion of OC in
425 the studied topsoils resided in mineral-organic associations (35–81%), whereas OC occluded in
426 aggregates amounted to 7–24%, with a lower share under cropland than forest as determined by density
427 fractionation (*Kirsten et al., 2021*). The low clay–high Fe cropland had an OC content more than twice
428 larger than that of the low clay–low Fe cropland, but comprised a significantly smaller MWD. Thus, a
429 shift towards more macroaggregation, indicated by a larger MWD in certain mineralogical combinations,
430 did not result in higher total OC storage, like shown for other tropical soils (*Barthès et al., 2008; Bartoli et*
431 *al., 1991; Spaccini et al., 2001*). The OC content of the > 4 mm aggregate and 2–4 mm aggregate fractions
432 accounted for 42 to 73% of the total soil OC content (Figure 1b). This, however, does not *per se* indicate
433 the relevance of macroaggregation for OC storage in weathered tropical soils like proposed by others
434 (*Feller and Beare, 1997; King et al., 2019; Six et al., 2002*). The high clay–low Fe forest with the highest
435 share in > 4 mm and 2–4 mm aggregates had significant lower OC contents in these fractions than most
436 other mineralogical combinations. Comparing forest with cropland soils (Table 2), we observed
437 significantly reduced OC contents in the majority of macroaggregate fractions of the low clay–low Fe and
438 high clay–high Fe croplands, as reported in other studies (*Blanco-Canqui and Lal, 2004; Lobe et al.,*
439 *2011*). In contrast, fewer changes of aggregate-associated and total soil OC contents was observed in the

440 low clay–high Fe combination, despite it experienced the strongest disaggregation of the largest
441 macroaggregates (Figure 1a and Figure 2). We conclude that larger amounts of > 2 mm aggregates or
442 higher stability during wet sieving not automatically translates into higher aggregate-associated OC
443 contents, as reported for Ferralsols (*Maltoni et al., 2017*). Given all these observations and the fact that
444 occluded OM determined by density fractionation was mostly of subordinate relevance, particularly in
445 croplands, OC storage in study soils seems rather disconnected from their aggregation status.
446 Consequently, the loss of large aggregates and the mass redistribution into smaller aggregate size fractions
447 does not automatically imply a loss of soil OC, because a substantial part of the OC in aggregate fractions
448 is bound to minerals with a higher persistence against land-use change (*Kirsten et al., 2021*). Here, density
449 fractionation could shed more light on the nature and quantity of OM located in certain aggregate size
450 fractions.

451 Microaggregates contained the highest OC content per unit of mass for almost all mineralogical
452 combinations, depth increments, and land uses (Table 2). This is in line with the findings of *Chenu* and
453 *Plante* (2006) and *Lobe et al.* (2011) that microaggregates can significantly contribute to OC storage. As
454 aggregates were isolated by dry sieving, these microaggregates were not located inside larger aggregates,
455 rendering them principally better accessible for OC allocation. Particularly OC contained in the
456 < 0.25 mm aggregates of the low clay–high Fe combination revealed a strong persistence against land-use
457 change, which explains well the unaltered soil OC contents upon land-use change.

458

459 **5. Conclusions**

460 Classification of soils into mineralogical combinations of aluminous clay and pedogenic Fe oxides
461 revealed significant effects of mineral constituents on soil structure and related OC storage in weathered
462 tropical soils. Despite that, overall patterns across combinations were more similar than different, *i.e.*,
463 always comprising a high level of macroaggregation and aggregate stability. Aggregates > 4 mm of the
464 low clay–low Fe and high clay–high Fe combinations were less affected by land-use change, thus
465 pedogenic Fe in a certain relation with aluminous clay (0.13 to 0.23) seems beneficial to maintain the
466 structural integrity of macroaggregates. Despite the high physical stability, OC contents of
467 macroaggregates declined substantially in most mineralogical combinations during forest–cropland
468 conversion. This highlights the fact that structural integrity of macroaggregates during land-use change
469 cannot be equated with OC persistence. For the low clay–high Fe combination, substantial destruction of
470 > 4 mm aggregates during land-use change due to agricultural management was also not accompanied by
471 higher OC losses. Hence, we must reject our initial hypothesis that the mineralogical combination that
472 results in the greatest aggregate stability best preserves OC during the conversion from forest to cropland.
473 Thus, the formation of macroaggregates cannot be considered as a main stabilization process for OC in
474 strongly weathered soils of the humid tropics. We suggest that the formation of mineral-organic
475 associations as part of the aggregate size fractions is the most important process that preserves OC during
476 land-use change in these soils.

477 **7. Author contribution**

478 KK, RM, MK, and KHF designed the project. MK, KK, RM, DNK, and KHF collected soil or data to
479 supported the sampling campaign. MK, KK, RM, and KHF evaluated data and all authors conducted a
480 thorough critical review of the manuscript. MK, KK, and RM wrote the manuscript with contribution of
481 all authors.

482

483 **8. Competing interests**

484 The authors declare that they have no conflict of interest.

485

486 **9. Acknowledgements**

487 We are grateful to the officials of Amani Nature Reserve who supported the field campaign in February
488 2018. Aloyce Mkongewa enthusiastically assisted fieldwork. We are also indebted to Gisela Ciesielski,
489 Manuela Unger, Mandy Meise, Tobias Krause, Thomas Klinger, Gudrun Nemson-von Koch, and
490 Christine Krenkewitz for laboratory support and analytical work. Finally, the authors would like to thank
491 the two reviewers for their comprehensive reading of the manuscript and constructive suggestions for its
492 improvement. This study was supported by grants of the Deutsche Forschungsgemeinschaft (DFG): FE
493 504/15-1, KA 1737/16-1, and MI 1377/11-1.
