Abstract. Land use is known to exert a dominant impact on a range of essential soil functions like water retention, carbon sequestration, organic matter cycling and plant growth. At the same time, land use management is known to have a strong influence on soil structure, e.g. through bioturbation, tillage and compaction. However, it is often unclear whether differences in soil structure are the actual cause for differences in soil functions or just co-occurring.

20 This impact of land use (conventional and organic farming, intensive and extensive meadow, extensive pasture) on the relationship between soil structure and short-term carbon mineralization was investigated at the Global Change Exploratory Facility, in Bad Lauchstädt, Germany. Intact topsoil cores (upper 10 cm, n=75) were sampled from each land use typetypetypes at the early growing season. Soil structure and microbial activity were measured using X-ray computed tomography and respirometry, respectively.

25 Grasslands had aDifferences in microstructural properties between land uses were small in comparison to the variation within land uses. The most striking difference between land uses was larger macropore diameters in grassland soils due to the presence of large biopores that are periodically destroyed in croplands. Grasslands had larger amounts of particulate organic matter (POM), including root biomass, and also greater microbial activity than croplands, both in terms of basal respiration and rate of carbon mineralization during growth. This was caused by a larger amount of particulate organic matter (POM) in the topsoil of grasslands. The frequently postulated dependency of basal respiration on soil moisture was absent even though some cores were apparently water limited. This finding was related to microenvironments shaping microbial hotspots where the decomposition of plant residues was obviously decoupled from water limitation in bulk soil. Differences in microstructural properties between land uses were surprisingly small, mainly due to huge variability induced by patterns of compacted clods and loose areas caused by tillage in cropland soils. The most striking difference was larger macropore diameters in grasslands soil due to the presence of large biopores that are periodically destroyed in croplands.

Variability of Variation in basal respiration among all soil cores amounted to more than one order of magnitude (0.08-1.42 $\mu\text{g CO}_2\text{-C h}^{-1} \text{ g}^{-1}$ soil) and was best **described explained** by POM mass ($R^2=0.53$, $p<0.001$). Predictive power was hardly improved by considering all bulk, microstructure and microbial properties jointly. The predictive power of image-derived microstructural properties was low, because aeration was not limiting carbon mineralization and was sustained by pores smaller than the image resolution limit ($<30\mu\text{m}$). **The frequently postulated dependency of basal respiration on soil moisture was not evident even though some cores were apparently water limited, as it was likely disguised by the co-limitation with POM mass. This finding was interpreted towards microbial hotspots which form on decomposing of plant residues and which are decoupled from water limitation in bulk soil.** The rate of glucose mineralization during growth was explained well by substrate-induced respiration ($R^2=0.84$) prior to growth, which was in turn correlated with total microbial biomass, basal respiration and POM mass and again not affected by pore metrics.

These findings stress that soil structure had little relevance in predicting carbon mineralization in well-aerated soil, as this predominantly took place in microbial hotspots around degrading POM that was detached from the pore structure and moisture of the bulk soil. Land use therefore affects carbon mineralization in well-aerated soil mainly by the amount and quality of labile carbon.

50 1. Introduction

Soil respiration is an important link in the global carbon (C) cycle as it releases soil-borne organic carbon back into the atmosphere. **Organic C is protected against mineralization by reduced bioavailability through sorption on reactive minerals and physical protection in the soil pore network (Dungait et al., 2012;Schmidt et al., 2011).** The balance between C storage and C mineralization is thought to arise from an interplay between the molecular diversity of organic compounds and the spatial heterogeneity and temporal variability of environmental conditions in soil (Lehmann et al., 2020). Soil moisture and temperature are considered to be the environmental factors that exert a dominant control on C mineralization. **The influence is either directly direct through their control on reaction and diffusion rates or indirectly indirect through their effect on biomass production including plants and microfauna (Davidson et al., 2006).** Land use related changes in soil management can affect carbon mineralization in all of the aforementioned ways, i.e. through changes in thermal properties, water retention and consumption as well as biomass production. The variability in carbon mineralization is thought to arise from differences in substrate accessibility and soil aeration due to soil structure changes that modify the size and spatial distribution of pores and, as a consequence, the exposure of organic carbon to microbial decomposition (Dungait et al., 2012;Schmidt et al., 2011). Despite their obvious importance, larger-scale C cycling models are just starting to incorporate these microscale interactions (Yan et al., 2018;Ebrahimi and Or, 2018;Meurer et al., 2020).

65 A major hurdle to fully account for structural constraints on C mineralization is the methodological challenge to combine incubation studies with the investigation of soil microenvironments on identical samples. A viable option in this respect has emerged with microstructure analyses of incubated soil samples via X-ray computed microtomography (X-ray CT). By employing this combination of methods, the mineralization rate of the stable soil C pool turned out to **depend on correlate**

with the average pore neck diameter as a proxy for soil aeration for a loamy forest soil with a range of bulk densities that was brought to the same water saturation and incubated for 35 days (Bouckaert et al., 2013). Long-term incubations (127 days) of silt-loam soils with fixed bulk soil densities (1.4 g/cm³) and soil moisturewater contents (matric potential pF 2.5, water content 25 vol%), but very different internal structure (undisturbed, sieved, slaked) exhibited no differences in C mineralization rate after passing of the initial CO₂ flush caused by disturbance irrespective of substrate amendment (fructose, vanillin) (Juarez et al., 2013). Even though the macropore space scanned at a coarse resolution (32 μ m32 μ m) differed vastly between the structure treatments in terms of volume fraction and morphology, the pore space scanned at a finer resolution of 3 μ m3 μ m was quite similar, indicating. This indicated that the continuity of air and water at this soil moisture and thus the supply with oxygen and dissolved substrates was too similar to evoke differences in C mineralization despite differences in microbial abundance and community composition at the end of incubation. Soil aggregates (5–6 mm Two months of pre-incubation were chosen by Juarez et al. (2013) to omit the initial CO₂ flush caused by disturbance that is known to last for more than a week (Herbst et al., 2016). Soil aggregates (5–6 mm) from a clay soil, adjusted to a matric potential of pF 2.7 and incubated for 1 day showed a six-fold variation in soil respiration (normalized for differences in organic C content) at only a two-fold difference in organic carbon content (Rawlins et al., 2016). The internal pore surface area was best suited to explain the difference in respiration, yet only at a fairly moderate correlation coefficient (R^2 =0.44). It has been suggested that the magnitude of protection of soil organic C against mineralization results from the interplay of how much C enters the soil as plant biomass and exudates and how much of this newly added C is subsequently protected (Kravchenko et al., 2019). This balance may be very different between different land uses and was shown, in a case study comparing continuous corn, switchgrass, and native succession, to depend on the plant-stimulated pore formation in the size range of 30–150 μ m as these = 150 μ m. These pores are associated with the highest enzyme activities and thus the highest capacity for microbial transformation of carbon sources (Kravchenko et al., 2019). In summary, microstructure analysis may help to improve the prediction of carbon mineralization rates in intact soil. However, from the previous findings it is already evident that a true gain in predictability is not always warranted and depends on the environmental conditions encountered during incubation. We therefore measured soil respiration under contrasting land uses (cropland vs. grassland) that are known to induce various soil structures. Soil respiration was measured in intact soil cores after exposing them to very different environmental conditions: 1. basal respiration at field moisturewater saturation and 2. substrate-induced respiration (SIR) at higher soil moisture. The rationale for repeated incubations of intact soil cores at different moisture and substrate availability was to provide a more complete picture of links between microstructural properties and carbon mineralization. Our objectives were to 1) investigate differences in soil structure and C mineralization induced by land use and 2) to explore as to how to-far microstructural properties are required to explain variation in carbon mineralization rates. Bearing in mind that such microstructure analyses are laborious and time consuming, we 3) aimed to assess in how far these microstructural properties can be replaced by easily available bulk properties like water saturation, bulk density or particulate organic matter content.

2. Materials & Methods

2.1. Site description

The Global Change Experimental Facility (GCEF) is situated at the field research station of the Helmholtz Centre for Environmental Research in Bad Lauchstädt, Germany (51°23'33.1"N 11°52'56.5"E, 121 m a.s.l.). The site is characterized by

105 a sub-continental, temperate climate with an annual mean temperature of 9.7 °C (1993-2013) and a mean annual precipitation of 525 mm (1993-2013). The soil type is a fertile Haplic Chernozem with on average 21% clay, 69% silt, and 10% sand in the topsoil layer (Altermann et al., 2005). The GCEF platform was established in 2013 and combines five land use types with two climate treatments (Schädler et al., 2019). The full design comprises 50 large field plots (16x24 m), which are arranged in ten blocks. Five of the blocks are subjected to ambient climate, while five are exposed to conditions of

110 a projected future climate. The five land use types ~~were in each climate scenario are replicated five times~~, randomly assigned to the five plots of each block ~~and~~. ~~They~~ include (1) conventional farming (CF), (2) organic farming (OF), (3) intensively

managed grassland ~~used cut~~ by mowing (IM), (4) extensively managed grassland ~~used cut~~ by mowing (EM) and (5) extensively managed grassland used as sheep pasture (EP). ~~Each treatment combination (land-use x climate) is replicated five times across the experimental platform.~~ The land use types are managed according to common practices for Central

115 Europe and include the ~~full~~ set of respective management measures (fertilizer and pesticide application, soil and plant cultivation). On CF plots a rapeseed-wheat-barley crop rotation is cultivated, whereas rapeseed is replaced by a legume in

OF. ~~The management of both croplands include conventional soil cultivation.~~ For IM, a species-poor mixture of forage grasses was established, consisting of *Lolium perenne* (20 %), 'Festulolium' (50 %), *Dactylis glomerata* (20 %) and *Poa pratensis* (10 %). In contrast, a mixture of 56 plants species from the local gene pool, containing legumes, grasses and non-

120 leguminous dicots species, was sown in both extensively managed grasslands (EM, EP). ~~The management of both croplands include conventional soil cultivation.~~ For further details on treatments and management we refer to Schädler et al. (2019).

~~Importantly, both croplands were plowed (18th of February) and further cultivated with a rotary cultivator (4th of March) few months before sampling.~~

2.2. Field sampling

125 We focused on the 25 plots (5 land use types x 5 field replicates) exposed to ambient climatic conditions. Sampling took place in early May 2020, when plants in the cropland plots (CF: rapeseed, OF: white clover) were at the beginning of

130 vegetation season. Intact soils cores were sampled with ~~aluminum~~ ~~aluminium~~ rings (v=100cm³, h=4cm) in a depth between 3 and 10cm. Three soil cores were taken from each plot ~~totaling~~ ~~totalling~~ 75 samples. After sampling, the soil cores were stored in bags under cool conditions, including the ~~imaging procedure, until respirometry, image acquisition, until~~

~~respirometry. Importantly, both croplands were plowed (18th of February) and further cultivated with a rotary cultivator (4th of March) few months before sampling.~~

2.3. Bulk properties

Bulk density (ρ) and initial water saturation (θ/ϕ) were determined by weighing the soil cores before respirometry, as well as after drying the cores at 105°C for 48 hours following respirometry. Thereby, bulk density was calculated with the final

135 soil dry weight divided by the core volume (100 cm³). Water content (θ) in the collected soil cores ~~were~~was determined by mass differences of initial and final soil weights. Water saturation levels were obtained by normalizing the ~~total~~water ~~volumecontent~~ (θ) with total soil ~~pore~~volume ~~porosity~~ (ϕ). Air contents (θ_a) during substrate-induced respiration were calculated from the difference between ϕ and $\theta + \theta_{gl}$ after substrate-induced respirometry, with θ_{gl} representing the volumetric glucose solution content. Finally, ~~to measure the contents of particulate organic matter (POM), roots and plant litter were washed out of the soil cores using~~were dispersed during a wet sieving procedure (0.63 mm mesh size~~)~~) to extract inorganic (sand, stones) and organic (roots, plant litter) components. Inorganic and organic components were subsequently separated by hand and POM mass (m_r) was determined after drying for 48 hours at 70°C. This POM mass does not only include organic material from previous years, but also the fresh root biomass that was cut off during sampling and only started to decay during incubation. Additional explanatory variables, i.e. total C and C:N ratio, were determined for all plots

140 145 using soil samples collected at the 20th of March 2020 in the course of the continuous GCEF monitoring program. Total carbon and nitrogen contents were measured from sieved (2 mm) fine soil using an elemental analyzer (Elementar Vario EL III, Elementar, Hanau, Germany~~)~~) and used to calculate C:N ratios. Total carbon was reported as total organic carbon content (TOC) as the inorganic carbon content in the topsoil is negligible.

2.4. Microstructure analysis

150 All soil cores were scanned with X-ray computed tomography (X-tek XT H 225; Nikon Metrology) at 150kV and 170 μ A with 2500 projections and two frames per projection. A 0.3 mm copper filter was used to reduce beam hardening artefacts. Tomograms were reconstructed with 8-bit grayscale and 30 μ m voxel size with the X-tek CT Pro software (Nikon Metrology). Gray scale contrast was stretched by setting the darkest and brightest 0.2 percentile to 0 and 255, respectively. All image processing was carried out with the Fiji bundle for ImageJ (Schindelin et al., 2012) and associated plugins. Image 155 noise was reduced with a non-local means filter (Buades et al., 2005) prior to edge enhancement with an unsharp mask filter (Schlüter et al., 2014). The grayscale images were segmented into pores and background with Otsu's method (Otsu, 1975) for pore structure analysis at the original resolution. Pore metrics of interest include visible porosity (ϕ_{vis}), surface area density (a), mean breadth (b) and the Euler number density (χ), which were determined with the MorphoLibJ plugin (Legland et al., 2016). The pore topology metric χ counts the number of isolated pore objects positively and the number of 160 redundant connections negatively, so that poorly connected and well-connected pore structures induce positive and negative, χ , respectively (Vogel et al., 2010)(Vogel et al., 2010). A complementary connectivity metric is the connection probability Γ , which reflects the probability of two randomly chosen pore voxels to belong to the same pore cluster. Pore clustering was carried out with the connected components labelling in MorpholibJ (Legland et al., 2016). The average pore distance (d) was determined based on the Euclidean distance transform of soil voxels, i.e. shortest distance to a pore for all background 165 voxels. The average pore diameter (\emptyset) was determined with the maximum inscribed sphere method termed Local Thickness in ImageJ (Fig. 1b). The critical pore diameter \emptyset_c reflects the bottleneck diameter at which pore continuity from top to bottom is lost (Koestel, 2018).

In addition to these pore metrics, the volume fraction of particulate organic matter (POM) was determined via supervised, machine-learning based image segmentation with ilastik (Sommer et al., 2011). (Berg et al., 2019). A parallel random forest 170 classifier was used to segment pores, POM, soil matrix and rocks (Fig. 1b) by deploying a multi-dimensional feature space that included the original gray values as well as gradient (1st derivative of gray values) and texture information (2nd derivative of gray values) after Gaussian smoothing with a strength of $\sigma=[0.3,0.7,1.0]$. In this way, characteristic traits of each material like the aperture of cracks, the inherent heterogeneity of the organic fabric or the homogeneity of quartz grains was harnessed for material detection. The classifier was trained with a few test lines for each material class in a small 175 number of images (six out of 75). The images had to be downsampled to a voxel size of $60\mu\text{m}$ to make segmentation tractable.

2.5. Respirometry

Basal respiration (p_B) rates were determined from intact soil cores (100cm^3) at 22°C and fieldthe water saturation in the field 180 at the date of sampling using an automated respiration analyzer (Respicond V, Sweden). Emitted CO_2 is trapped in 10 mL of 0.6 M KOH solution and measured through the increase in electric impedance at a given voltage. Soil cores were incubated for two days and the average respiration rate determined for the period after some initial equilibration. Respirometry was 185 conducted on 60 out of 75 soil cores distributed evenly among cropland (CF and OF, 15 each) and grassland soil (IM, EM and EP, 10 each).

The same 60 soil cores were subsequently amended with a glucose containing mineral salt solution (glucose – 0.28 M ; $(\text{NH}_4)_2\text{SO}_4$ – 0.07 M ; KH_2PO_4 – 0.025 M ; MgSO_4 – 0.125 M) to measure substrate-induced respiration (SIR) (Anderson and 190 Domsch, 1978) and to infer microbial growth kinetics from it (Stenström et al., 1998; Panikov, 1995). The solution was added to the field moist soil cores in two steps. First, the bottom of the soil cores was covered with a textile before placing them for 30min in the glucose-nutrient bath with a shallow water table so that the solution was sucked in by capillary rise. Thereafter, 4 mL of the glucose-nutrient solution were added from the top of the core with a pipette and allowed to infiltrate for 10min. Finally, the fully saturated soil cores were drained from macropores with low capillarity by placing the soil cores 195 on a dry sand bed for 10min. After drainage, soil cores were placed into the Respicond for 48h at 22°C . The absorbed volume of glucose-nutrient solution was measured after the SIR approach via weight loss upon oven-drying as described above and accounting for the antecedent field moisture-water saturation. The amount of absorbed glucose solution was different for every soil core and increases with decreasing field water content θ and increasing porosity ϕ . However, for all soil cores glucose-C was provided in excess, i.e. the CO_2 uptake capacity of the respirometer was exceeded with only a fraction of the mineralized C. The time, t_{exc} , until the capacity of the respirometer was exceeded ($73\text{mg CO}_2\text{-C}$ at the given KOH concentration), was determined for every soil core (Fig. 2). In addition, an empirical model for microbial growth kinetics (Wutzler et al., 2012) of the form

$$p_{SI}(t) = A + Be^{\mu t} \quad (1)$$

200 was fitted to the substrate-induced growth respiration stage of each time series using ModelMaker-3 software (SB Technology Ltd), [where](#). p_{SI} is the substrate-induced respiration rate at time t , A is the growth-independent CO_2 release rate, B is the growth-dependent CO_2 release rate and μ is the microbial specific growth rate. The identification of a lag phase and initial substrate-induced respiration prior to growth ($p_0 = A + B$) was obstructed by uncertain data during initial equilibration of the CO_2 readings and had to be substituted by data extrapolation and a subjective definition of a lag phase as shown in Fig. 2. The active microbial fraction was determined as

$$r_0 = \frac{AMB}{TMB} = \frac{B(1-\lambda)}{A+B(1-\lambda)} \quad (2)$$

205 where AMB is the active microbial biomass participating in growth, TMB is the total microbial biomass and λ is a basic stoichiometric constant of 0.9 during unlimited growth (Akimenko et al., 1983)

2.6. Statistical Analysis

210 Statistical [analyses](#) were performed with R (R Core Team, 2018) and figures were produced with package `ggplot2` (Wickham, 2016). Normality of residuals and homogeneity of variances were tested with the Shapiro-Wilk test and Levene test at a level of $p>0.05$, respectively. If these criteria were met, then one-factorial ANOVA followed Tukey HSD Postdoc test were carried out to identify significant differences between land use types at a level of $p<0.05$ using the `agricolae` package (de Mendiburu, 2019). If the criteria were not met, then a non-parametric Kruskal-Wallis test was carried out at a level of $p<0.05$ with the same package. For simplicity, Pearson correlations between two variables are reported, irrespective whether normality in the residuals is fulfilled.

215 Partial least square regression was conducted in order to identify the amount of explained variability of a target variable (p_B, t_{exc}) by a combination of explanatory variables. [This Pseudo-replicates, i.e. the 2 – 3 soil cores from the same plot, were considered individually to explore the full range of variation in target variables. Explanatory variables, which were only available as plot averages \(TOC, C:N ratio\) were therefore not considered. Partial least square regression](#) was either done for the pooled data set (all land uses, $n=60$) or individually for grassland soil cores (IM+EM+EP; $n=30$) and cropland soil cores (CF+OF, $n=30$). To do so, the target variables (p_B, t_{exc}) and explanatory variables ($\rho, \theta/\phi, m_r, \phi_{vis}, a, b, \chi, \Gamma, d, \emptyset, \emptyset_c, p_o, \mu, r_o$ (and p_B for target variable t_{exc})) [see Table 1 for meaning of symbols](#)) were tested for normal distribution [and if. If needed, they were](#) transformed to reach normal distributions and linear relationships of data (i.e., a logarithmic transformation or a logistic transformation ($\text{logit}(x) = \log(x/(1-x))$)).

220 There was collinearity between many variables of the present study, which excludes simple linear regressions to explore the variability of basal and substrate-[induced](#) respiration. Partial least square regression (PLSR) with Leave-One-Out Cross-validated R^2 allows for collinearity between variables and identifies the most important explanatory variables to predict the target variables. Permutation testing served to describe components that best explained p_B and t_{exc} . Robust confidence intervals against deviations from normality were obtained from bootstrapping (R package `boot` v. 1.3-24) (Davison and Hinkley, 1997; Canty and Ripley, 2019). The smoothed bootstrap was used by resampling from multivariate

kernel density (R package kernelboot v. 0.1.7) (Wolodzko, 2020) as sample sizes were relatively small (60 in pooled and 30 in grouped data). The BCa bootstrap confidence interval of 95% of R^2 was a measure to explain the variability in each response variable (Efron, 1987).

PLSR was repeated for a series of simplifications: a) complex model with all bulk, microstructural and microbial explanatory variables (θ/ϕ for p_B and θ_a as well as p_B for t_{exc}); b) complex model including only bulk and microstructural properties (n=111 for p_B and n=12 for t_{exc} , excluding p_o , μ , r_o), c) a VIP model that includes only the most informative variables identified by PLSR (n=3-5; composition varies between target variables and land use combinations), d) manually selected (pairs of) explanatory variables selected based on expert knowledge that serve as a base line reference (n=1-2; choice depends on target variables).

3. Results

3.1. Bulk properties

At the early growing season (May) the young plants in both croplands (CF, OF) had transpired less water than the permanent vegetation cover in the three grasslands (IM, EM, EP) resulting in a significant difference in field water saturation (Table 1). In fact, the water contents in grassland were already close to the permanent wilting point at that soil depth ($\theta = 0.09$ mm³/mm³ at pf 4.2, personal communication by Max KoehneKöhne). The POM content ($>0.63\text{mm}$)63 mm, mainly comprising roots and old plant residues incorporated by plowing, was significantly lower in the farmingcropland plots (CF, OF) than in the grassland plots (IM, EM, EP) (Table 1). The TOC content followed the identical order, whereas soil C:N ratios did not differ significantly between any of the land uses (Table 1). Surprisingly, there was no difference in average bulk density between any of the land uses (Table 1). However, in farmingcropland plots the variability in bulk density was greater than in grasslands. This was triggered by randomized sampling locations within a plot that may either fall into areas loosened by plowing or areas compacted by traffic. The volumetric air content in the soil cores after the uptake of glucose solution was on average around 0.1 (mm³/mm³) for all land uses. Thus, if oxygen supply was limited during growth on glucose in intact soil cores, it was on average the same for all land uses.

3.2. Microstructure properties

The visible microstructure in the topsoil differed vastly between land uses but also among soil cores of the same land use. The 2D slices of selected X-ray CT images in Fig. 3f are not meant to be representative for the land use, but exemplary to show. Instead, they cover the entire variability in size and volume fraction of pores as well as the volume fraction of particulate organic matter. The visible porosity deesdid not differ across land uses, but hashad a much higher variability in farmingcropland plots (Fig. 3a, Table 1). VisibleThe regression between visible porosity ($>0.03\text{mm}$) and bulk density were strongly correlatedhad a high goodness of fit (Fig. 3b, $R^2=0.74$, $p<0.001$), since it is mainly the macroporosity that is affected by soil management. There was a number of other pore metrics like surface area, mean breadth, Euler number and mean pore distance that also did not differ between land uses (Table 1). The mean pore diameter was significantly larger in grassland than in farmingcropland plots (Fig. 3c, Table 1), because a certain fraction of the pore space was contributed by large

biopores including taproot channels and earthworm burrows, which are periodically destroyed by plowing in farming plots. Likewise, the critical pore diameter was significantly larger in EP and EM than in OF and even lower in CF. Interestingly, the critical pore diameter in IM was more similar to that in OF, indicating that biopores in intensive meadow are less often 265 continuous from top to bottom. Following the pattern of the POM content (m_r), the POM volume was significantly higher in grassland than in cropland soil (Fig. 3d, Table 1). The correlationgoodness of fit between image-derived POM volume and POM content determined by wet sieving (Fig. 3e, $R^2=0.53$) was somewhat lower than correlationthat for independently 270 determined proxies for porosity discussed above. This iswas likely caused by incomplete POM detection by both methods and the differences in the lower size cut-off (downscaled image resolution of 0.06mm vs 0.63mm mesh size of sieve) as well as between mass density and volume density₂₇₀.

3.3. Respiration properties

Basal respiration at field moisturewater saturation was highest in extensive pasture and lowest in both farmingcropland plots with intermediate rates for both meadows (Fig. 4a, Table 1). BasalVariation in basal respiration correlated strongly could be well explained with variations in POM content (Fig. 4b, $R^2=0.53$, $p<0.001$) and only slightly less with POM volume density (275 $R^2=0.35$, not shown). Surprisingly, basal respiration was completely independent of initial water saturation when pooled across land uses, even though the entire range between supposedly critical dryness and optimal conditions was covered (Fig. 4c). Furthermore, basal respiration was independent of visible porosity (Fig. 4d)

Substrate-induced respiration in the first hours after glucose addition ($p_0 = A + B$) was up to 3.5 times higher in all 280 grasslands than in both farmingcropland treatments (Fig. 5a). The correlation between correspondence of basal respiration and initial substrate-induced respiration prior to growth was highly significant (Fig. 5b, $R^2=0.59$, $p<0.001$)and amounted to. The glucose addition resulted in a six-fold increase in respiration rates by glucose addition, which is in agreement with 285 previous incubation studies (Wardle and Ghani, 1995; Hund and Schenk, 1994) and. This increase indicated previous limitation of microbial activity in all collected soils due to substrate deficiency (Blagodatskaya and Kuzyakov, 2013). The correlationgoodness of fit deteriorated slightly ($R^2=0.31$, $p<0.001$), when those samples with exceptionally high p_B due to high root biomass and those samples with exceptionally low p_0 that might have been caused by insufficiently precise 290 estimation of lag time were disregarded.

Due to higher initial microbial activity, the added glucose was consumed much faster in grassland soils and reached the CO_2 uptake capacity of the respirometer much sooner as compared to cropland soils (Fig. 5c, Fig. S 1). The logarithm of this time 295 of capacity excess, t_{exc} , was tightly linked to p_0 (Fig. 5d, $R^2=0.84$, $p<0.001$) and to a similar extend to total microbial biomass TMB (not shown, $R^2=0.60$, $p<0.001$), which TMB is coupled with p_0 through eq. (2). Only two parameters of the model (eq. 1) that was fitted to the exponential increase in CO_2 release were different between grasslands and croplands (Table 1). The growth-independent respiration rate A and the growth-dependent respiration rate B (just as its sum p_0) were both significantly smaller in cropland soils, which accounts for the fact that initial CO_2 release rate directly after glucose

295 addition were lower. The microbial growth constant μ did not differ between land uses. Following the pattern of the total biomass, the active microbial biomass was higher in grasslands than in croplands. The variability in the active fraction of microbial biomass was, however, too high among replicates to evoke significant differences between land uses.

300 ~~In summary, six years of different land use induced significant changes in soil properties that are expected to change slowly (TOC content), while others remained unchanged (bulk density, C:N ratio). In addition, some land uses differed in soil properties that are expected to follow a seasonal pattern (e.g. POM volume, pore diameter) induced by different vegetation cover during a growing season and presence or absence of tillage. Finally, plots from different land uses also varied in terms of spatial heterogeneity. The combination of all these effects constitute a comprehensive dataset of soil structures for testing which minimum set of bulk and microstructure properties is required to predict soil respiration across a range microbial activities differing by at least one order of magnitude.~~

305 3.4. Prediction of respiration properties

310 ~~Many~~ Not all bulk and microstructure properties were relevant for explaining the observed variation soil respiration across land uses. In fact, many microstructural properties ~~correlate~~ correlated significantly among each other and with bulk properties (complete correlation matrix in Fig. S 2). Likewise, many respiration properties ~~correlate~~ correlated among each other (partly by definition and accounted for by only considering the independent variables p_B , p_0 , r_0 and μ in the following) and with microstructural and bulk properties (Fig. S 2). This collinearity among microstructural, bulk and microbial parameters is directly accounted for by partial least squares regression (PLSR) and quantified in biplots in the supporting information (Fig. S 3, Fig. S 4).

315 Simple regressions of basal respiration with selected bulk or microstructure properties in the previous section already highlighted the importance of POM content, m_r , for explaining the variability in basal respiration p_B ($R^2=0.53$, $p<0.001$).

320 325 The predictive power of m_r on p_B is reduced to a median R^2 of 0.34 by PLSR with data normalization and boot strapping. The predictive power of the complex model for basal respiration among all land uses only increased to $R^2=0.43$ when all abiotic and microbial variables were considered as explanatory variables (Fig. 76a), which a. This increase can mainly be attributed to a higher degree of explained variability in grassland soils (from $R^2=0.27$ to $R^2=0.53$). This gain in predictive power of the complex model can be attributed to was caused by the added information content of microbial parameters as its omission. This follows from the fact that a complex model in which microbial parameters are excluded (all- p_0 - r_0 - μ) results in a lower, almost identical had low predictive power like, similar to the simplest model with m_r only. Indeed, the VIP model for grasslands include p_o , m_r , θ/ϕ , ρ , and μ in descending order of importance. In general, the explained variability was higher for grasslands and very poor for cropland soils. The explained variability is increased by 0.1-0.2 in comparison to the bootstrapping median and reaches $R^2>0.60$, if supposed outlier samples are discarded by the Leave-one-out procedure. The surprisingly low information content of field water saturation is confirmed. The collinearity of many explanatory variables is indicated by similar directions in Fig. 7b. Only those parameters with long vectors at an angle sufficiently different from 0°

or 180° can provide meaningful, complementary information. The congruency of the direction of m_r with the scatter of grassland soils reflects the higher predictive power as compared to cropland soils water saturation in the field is confirmed.

The explained variability observed for the time of capacity excess, t_{exc} , after glucose addition is excellent for the full complexity model in the pooled data set ($R^2=0.93$, Fig. 87a). The model is better suited to explain the differences between grassland and cropland soils than to explain the variability within the two groups. A reduction in model complexity to the VIP model and even p_0 as the only explanatory variable does hardly reduce predictive power. The omission of microbial parameters (all- p_0 - r_0 - μ) reduces reduced the explained variability in t_{exc} of the pooled land uses to $R^2=0.58$, mainly. The coefficient of determination is lower because bulk and microstructure variables ~~can~~ could only explain the variability between grassland and cropland, and to a lower degree within grasslands, but not at all the variability in t_{exc} among cropland soils-as. This is shown exemplarily for pore surface area a . Differences in metabolic pathways due to different aeration of soil cores, e.g. between loosened and compacted soil in croplands, ~~can~~ could be ruled out as unaccounted source of variability, as these should have been clearly reflected in image-derived pore metrics like ϕ_{vis} and Γ and even more directly in air content θ_a . In fact, θ_a after glucose addition correlated less with the speed of glucose mineralization t_{exc} than θ/ϕ in the field prior to glucose addition did (Fig. S 2). The different clustering of grassland and cropland soils in the corresponding biplot (Fig. 8b) reflects again the better congruency of p_0 with the scatter among grassland samples than with the scatter among cropland samples.

4. Discussion

4.1. Land use impact on soil properties and respiration

Land use specific soil management affected soil structural properties, which showed particular large differences between grasslands and croplands. The lack of tillage in grasslands promotes promoted the continuity of large biopores formed by taproots and earthworms, which was reflected in larger average and critical macropore diameters (ϕ, ϕ_c , Table 1) (Schlüter et al., 2020). At the same time, the continuous cover with perennial vegetation and the lack of mechanical disturbance by tillage promoted the built-up of soil organic C in grassland topsoils (TOC, Table 1) (Poeplau and Don, 2013). Differences between grassland and cropland soil in terms of plant residues, root biomass as well as water saturation in the topsoil ($m_r, v_r, \theta/\phi$, Table 1) were likely related to the fact that crops were still in an early growth stage, and had not established a dense root network, which limits limited water uptake and transpiration at the time of sampling in May. This discrepancy would have been smaller for winter crops (Thorup-Kristensen et al., 2009) and are likely to vanish during a growing season (Schlüter et al., 2013; Perkins et al., 2014). A somewhat surprising result was the equal average bulk densities in all land uses, as tillage is known to reduce bulk density in topsoils (Strudley et al., 2008; Palm et al., 2014). A bulk density of 1.4 g cm⁻³ is rather typical for grasslands at the Bad Lauchstädt site (Altermann et al., 2005), whereas previously reported bulk densities of tilled soils in other field trials on site tend to be higher, in the range of 1.46-1.62 g cm⁻³ (Eden et al., 2012) or lower, in the range of 1.12-1.27 g cm⁻³ (personal communication, Max Koehne Kühne) depending on soil management and

360 sampling time. Bulk densities do not only undergo a seasonal variation, but are also spatially quite variable depending on whether or not remnants of old or recent wheel tracks are sampled (Roger-Estrade et al., 2004).

There were also subtle, but consistent differences within cropland and grassland treatments. Organic farming had significantly larger critical pore diameters (ϕ_c) and tended to have slightly higher POM volume densities (v_r , $p=0.106$), presumably due to the more prominent presence of large crop residues from the previous growing seasons. Indeed, OF had a 7.5% higher straw production compared to CF in 2019 (data from continuous GCEF monitoring program). This however, did

365 not entail significant differences in carbon mineralization under ambient conditions, field water saturations. In grasslands, basal respiration differed significantly in the order IM < EM < EP (Table 1), even though there were no clear differences in bulk properties, microstructural properties or microbial parameters derived from subsequent substrate-induced respiration between the two meadows and the pasture. The lower basal respiration of IM soil, compared to EM and EP soils, is likely caused by the lower root biomass, represented by the lower POM content in our study. However, none of the available data 370 sets could explain the observed differences between EM and EP. Thus, this difference is possibly caused by the microbial community structure and its trait composition which is known to affect C mineralization rates (Guo et al., 2020;Nazaries et al., 2015;Auffret et al., 2016). In addition, nutrient availability and C:N ratios of the decaying plant residues, in particular the cut-off roots, might have implications on carbon mineralization, but are not well represented by the C:N ratios measured in soil (Table 1).

375 In summary, six years of different land use induced significant changes in soil properties that are expected to change slowly (TOC content), while others remained unchanged (bulk density, C:N ratio). In addition, some land uses differed in soil properties that are expected to follow a seasonal pattern (e.g. POM volume, pore diameter) induced by different vegetation cover during a growing season and presence or absence of tillage. Finally, plots from different land uses also varied in terms of spatial heterogeneity. The combination of all these effects constitute a comprehensive dataset of soil structures for testing 380 which minimum set of bulk and microstructure properties is required to predict soil respiration across a range of heterotrophic respiration rates in intact soil cores differing by at least one order of magnitude (0.08-1.42 $\mu\text{g CO}_2\text{-C h}^{-1} \text{ g}^{-1}$ soil).

4.2. Controlling factors of respiration

385 The combined impact of bulk density, field water saturation and POM contents resulted in a huge variability of soil heterotrophic respiration in 100 cm³ of intact topsoil at field moisture totaling more than one order of magnitude (0.08-1.42 $\mu\text{g CO}_2\text{-C h}^{-1} \text{ g}^{-1}$ soil). This basal respiration The variation of basal respiration rates was best described by the POM content of the sample. The POM contents also differed by more than one order of magnitude (0.3-4.6 mg g⁻¹ soil) because 1) in croplands roots were still young and POM predominantly contributed by plant residues from the last growing season and 2) 390 due to spatial variability in root length density especially within grassland plots. Macroporosity (ϕ_{vis}) had no impact on basal respiration. This apparently contradicts previous studies, which showed that soil compaction reduced soil respiration

under various levels of water saturation (Liebig et al., 1995). A subsequent study revealed that this reduction of carbon mineralization was particularly strong in a loamy sand soil when bulk densities were higher than 1.5 g cm^{-3} and plant residues were present at the same time, whereas unamended soil or less compacted soil showed less of a response (De Neve and Hofman, 2000). Unamended soil or less compacted soil showed less of a response. In the present study those soil cores with high POM content had low bulk density and vice versa, implying countervailing environmental impacts on basal respiration which may have caused its indifference to macroporosity (ϕ_{vis}). Surprisingly, water saturation had no measurable effect on carbon mineralization, even though it was very low ($\theta/\phi < 0.2$) in some grassland cores. It is likely that the decaying root material, which started to decay after sampling retained enough water by natural absorbance (Kravchenko et al., 2017) and released easily degradable substrates through cell lysis after sampling to act as microbial hotspots despite the onset of substrate limitation in an otherwise dry soil. In general, the drier soil cores that were driest, also had the highest associated with higher POM volume ($R^2=0.39$, $p<0.001$), which counterbalanced the substrate limitation effect in bulk soil. In none of the soil cores was the initial water saturation high enough to induce a deficiency of soil aeration. A large part of air-filled porosity was not even resolved at a voxel size of $30\mu\text{m}$. That is why visible macroporosity (ϕ_{vis}) and all other pore metrics that are highly correlated with ϕ_{vis} (Fig. S 2) do not add any substantial predictive power for basal respiration, which is in accordance with previous findings (Juarez et al., 2013). In addition, since image-derived ϕ_{vis} and v_r are highly correlated with ρ and m_r (Fig. 3, Fig. S 2), they can be substituted by simple bulk properties without loss in predictive power. Our findings indicate that carbon mineralization in well-aerated topsoils that contain fresh POM is biologically driven and mainly governed by carbon availability (Kuzyakov et al., 2009) and less by abiotic processes (diffusion, desorption, chemical reactions) as proposed by the regulatory gate hypothesis (Kemmitt et al., 2008), at least not by access or diffusion limitation imposed by soil structure.

The question remains, which overlooked additional parameters could have substantially improved predictive power with respect to basal respiration. It is unlikely, that the POM distribution in space (clustering vs. even distribution) (Schlüter et al., 2019), which in principle could also be analyzed with X-ray CT, would have mattered, since the supply with oxygen for basal respiration was sufficient in all samples. Information on microbial diversity such as microbial functional gene abundance related to oxidative and hydrolytic enzymes was recently reported to add another 5-19% in predictive power and reduce model uncertainty by 55-71% (Guo et al., 2020). Furthermore, different microbial communities may exert different C mineralization rates due to different carbon use efficiency (Domeignoz-Horta et al., 2020). Local variations in organic matter quality and nutrient availability could also have played a role in carbon mineralization that was not accounted for in the PLSR analysis as that information was not available at the soil core level. For instance, the biodegradability of old crop residues and fresh, cut-off roots are likely to be very different.

The speed of CO_2 release (t_{exc}) after glucose addition was chosen as an additional target variable to provide a more complete picture of links between microstructural properties and carbon mineralization. The logarithm of this release time was highly correlated with the respiration rate at the beginning of incubation ($\log(t_{exc}) \sim p_0$, $R^2=0.84$, Fig. 5d) and total microbial biomass, which is derived from it (TMB , $R^2=0.60$, not shown). This causal relationship has to be log-linear, since the

substrate is consumed with exponential dynamics after growth sets in, whereas the The growth itself seems to be similar for all treatments (in terms of μ) indicating similarity in functional structure of microbial community and in intrinsic traits of dominating decomposers. In addition, limited oxygen supply at air contents of approx. $0.1 \text{ mm}^3 \text{ mm}^{-3}$ irrespective of land use (Table 1) likely impaired unlimited aerobic growth and thus inhibited differences in μ . If the growth rate μ , as the second 430 driver of CO_2 efflux next to initial activity (in terms of p_0 or TMB), would have differed more among soil cores, it would presumably have reduced predictive power of initial microbial biomass and required to take them jointly into account. Maximum microbial specific growth rate for unlimited aerobic growth in sieved, unconsolidated soils is considered as an eco-physiological indicator sensitive to climate conditions (Lipson et al., 2009; Salazar-Villegas et al., 2016), nutrient 435 availability (Loeppmann et al., 2020), soil types (Loeppmann et al., 2018), and stages of plant residues decomposition. 440 However, the sensitivity of μ to different land uses within the same soil type still remains to be tested. Destroying the intact structure is known to have a tremendous impact on microbial activity. Heterotrophic respiration is very different for sieved and intact soil at the same bulk density and soil moisture in the first weeks after disturbance (Herbst et al., 2016). Our results indicated that also the capacity to grow on glucose is constrained in intact soil structure, presumably by diffusion limitations 445 of the substrate or oxygen. Likewise, a faster growth in microsites may be disguised by a delayed CO_2 release due to CO_2 diffusion limitations in intact soil. Future studies that focus on this direct comparison will have to clarify this. The prediction of t_{exc} from independent bulk or pore metrics without microbial variables derived from the glucose experiment is still fairly good (all- p_0 - r_0 - μ in Fig. 8, $R^2=0.58$) thanks to the correlation of total microbial biomass with POM content (m_r), basal respiration (p_b) and even antecedent water saturation (θ/ϕ) despite being changed by glucose addition (Fig. S 2). There are some significant correlations between t_{exc} and microstructural parameters like F , ϕ , ϕ_c and v_r connection probability (Γ), 450 average and critical pore diameter (ϕ , ϕ_c) and POM volume density (v_r) (Fig. S 2). However, it is evident that the causal relationship is in fact linked to substrate-induced respiration as a function of total microbial biomass, and that these microstructural properties do not carry any additional information. If only simple bulk properties were used as explanatory variables, then m_r was again the most relevant parameter.

5.1. Conclusions

Land use exerted a strong influence on carbon mineralization in terms of basal respiration and glucose-induced respiration. This was mainly caused by the vastly different amount of particulate organic matter in terms of old plant residues and intact roots between grassland and cropland soils. Surprisingly, field water saturation had no effect on basal respiration, as the decomposition of particulate organic matter contributes a large share of CO_2 emissions, but is decoupled from the water saturation in the bulk soil. Microstructural properties did not improve the prediction of carbon mineralization, as soil aeration was not limiting carbon mineralization and was maintained by pores that are not resolved with X-ray CT. If strong correlations between microstructural variables and carbon mineralization were observed, then they did not arise from causation but collinearity, and could easily be replaced with cheap bulk properties without substantial loss in predictive 455

~~power. The POM content was the bulk property that described carbon mineralization best across all land uses under well-aerated conditions. This is likely to change for prolonged phases of high water saturation.~~

460 Additional incubation experiments after repeated sampling of the plots at different stages of the [crop rotation](#), growing season and different precipitation history, including the different climate scenarios of the GCEF, will provide a more comprehensive data set in the future. By this, the governing state variables responsible for carbon mineralization vary a lot more due to ~~different soil moisture, different plants within the crop rotation or by seasonally changing shoot-to-root C allocation ratios, seasonally changing soil POM contents brought about by roots and fresh litter, different soil moisture as well as varying shoot-to-root C allocation ratios of plants. Finally, a sizeable amount of basal respiration was likely contributed by the decay of cut-off roots that would not have occurred, if soil respiration was measured on-site. Such field CO₂ measurements with comparable spatial footprint and environmental conditions like in laboratory incubations would be an important step to gauge the effect of intact rhizosphere vs. decaying detritusphere on carbon mineralization.~~

465

470 [5. Conclusions](#)

To conclude, our findings confirmed the influence of land use on carbon mineralization and revealed the underlying drivers.. Surprisingly, neither water saturation in the field, which is one of the main drivers of basal respiration known for disturbed, soil, nor land-use specific microstructural soil properties improved the prediction of carbon mineralization. If strong correlations between microstructural variables and carbon mineralization were observed, then they did not arise from causation but collinearity, and could easily be replaced with cheap bulk properties without substantial loss in predictive power. The POM content, including root biomass and other plant residues, was the bulk property that described variation in basal respiration best across all land uses under well-aerated conditions. Thus, our findings indicated that in intact soil cores, the decomposition of particulate organic matter, in particular the root residues that started to degrade after sampling, contributed a large share of CO₂ emissions, which masked the commonly described variation of C mineralization related to soil water saturation. The POM content also exerted a strong impact on the speed of glucose mineralization. This is because POM governed the initial microbial biomass, whereas the growth on glucose was equally constrained in all soil cores by diffusion limitations imposed by the intact pore structure.

720 **Figure 1:** Visualization of image processing steps for a 2D section of an X-ray CT image from a) the gray scale data to b) image segmentation results based on supervised, machine-learning based segmentation (pores yellow, POM pink, matrix green, rocks brown) and c) pore diameters based on local thickness. The sample was selected from an extensive pasture plot.

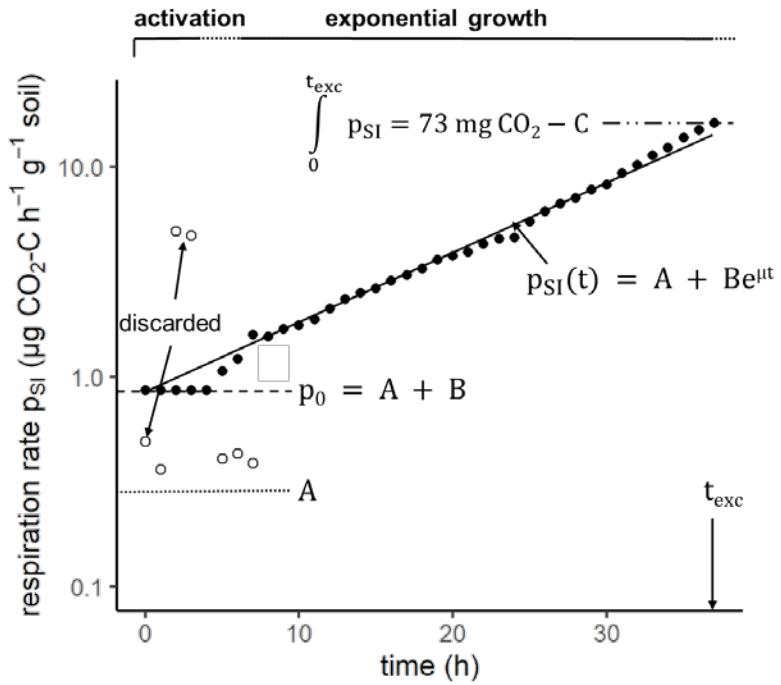

Figure 2: Example of a time series of CO_2 release after glucose addition at $t=-1\text{h}$ and first measurement at $t=0\text{h}$. The fluctuations in CO_2 readings during the first hours (empty circles) were discarded and replaced by a constant substrate induced respiration rate p_0 during an initial lag phase. The parameters μ , A , B and p_0 are derived from a model fit, whereas t_{exc} (time until a total of 73mg $\text{CO}_2\text{-C}$ was respired) is directly calculated from the time series.

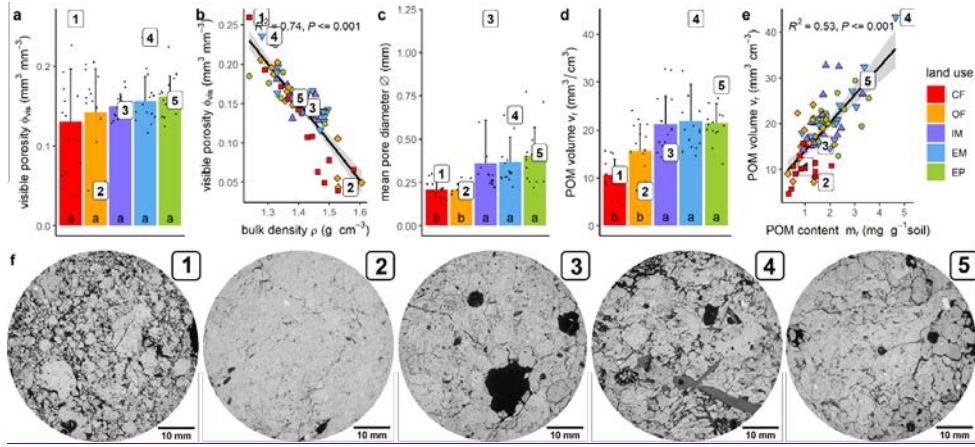

Figure 3: Selected microstructure properties (a, c, d) and relation to selected bulk properties (b, e) for different land uses. Columns and error bars represented mean and standard deviation at the plot level (n=5), whereas dots represent individual soil cores. Numbered dots in subfigures a-e correspond to the five selected X-ray CT samples, for which 2D sections are shown below. Different letters in barplots (a,c,d) indicate significant differences (p<0.05) between land use types.

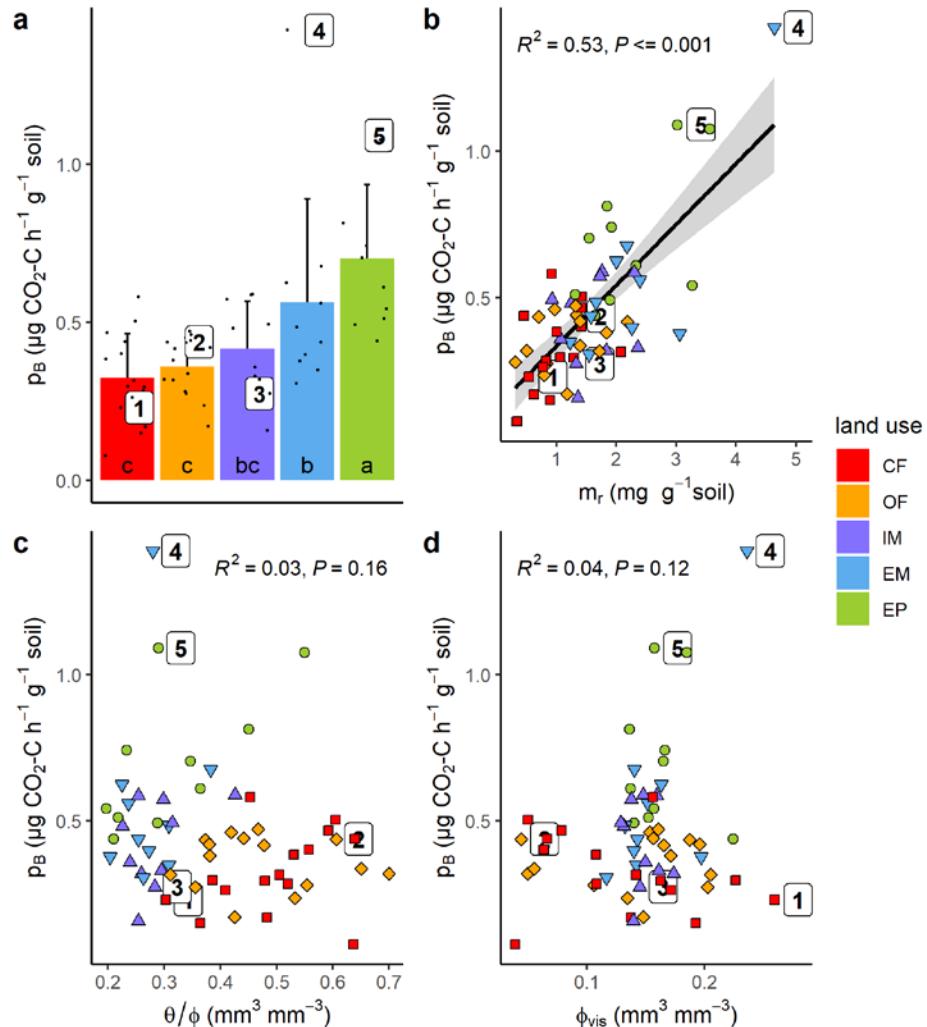

Figure 4: a) Basal respiration (p_B) as a function of a) land use, b) POM mass (m_r), c) field water saturation (θ/ϕ) and d) visible porosity ($>30\mu\text{m}$) (ϕ_{vis}). The numbered dots correspond to the samples depicted in Fig. 3f. Different letters in the barplot (subfigure a) indicate significant differences ($p < 0.05$) between land use types.

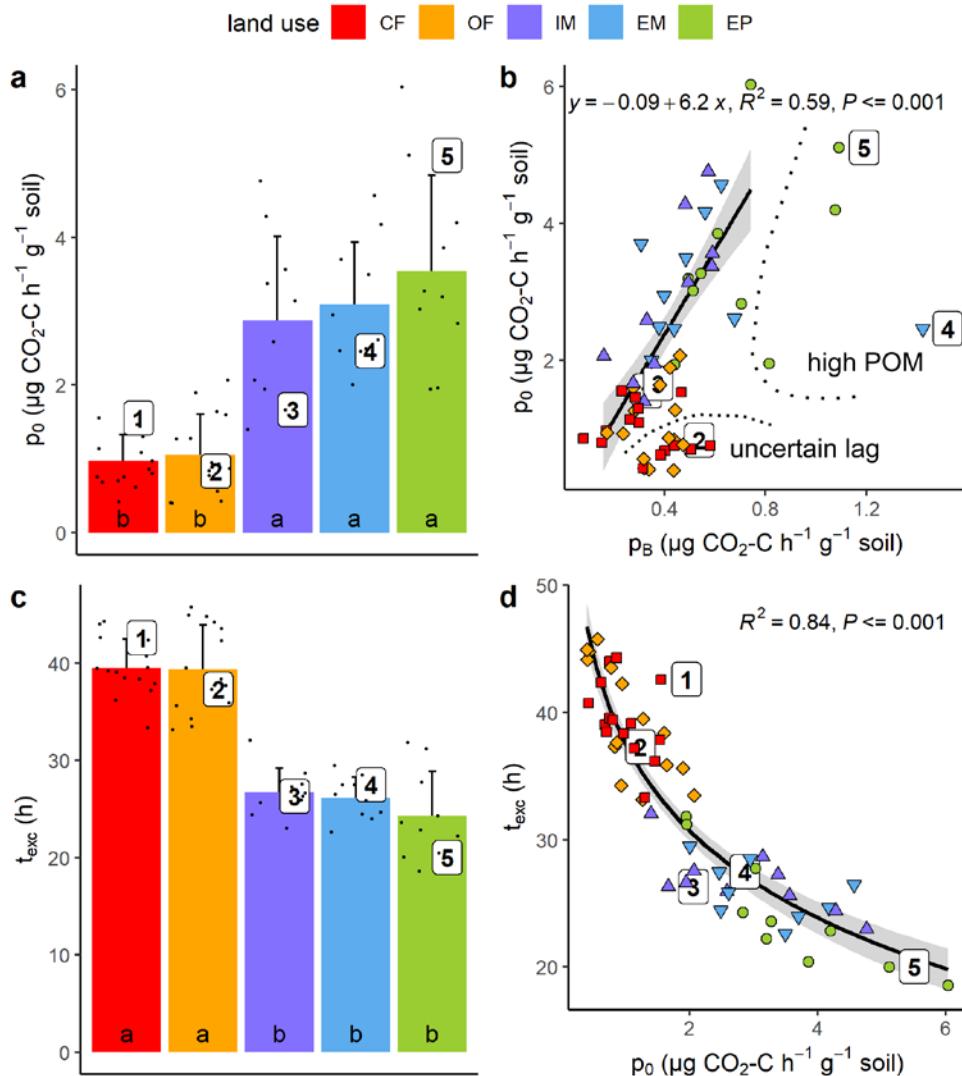

Figure 5: Initial substrate-induced respiration prior to growth (p_0) as a function of (a) land use and (b) basal respiration (p_B) as well as time until capacity excess of the respirometer (t_{exc}) as a function of (c) land use and (d) substrate induced respiration (p_0). High POM and uncertain lag in (b) indicate those samples that have been excluded from regression analysis. Different letters in barplots (a,c) indicate significant differences ($p < 0.05$) between land use types.

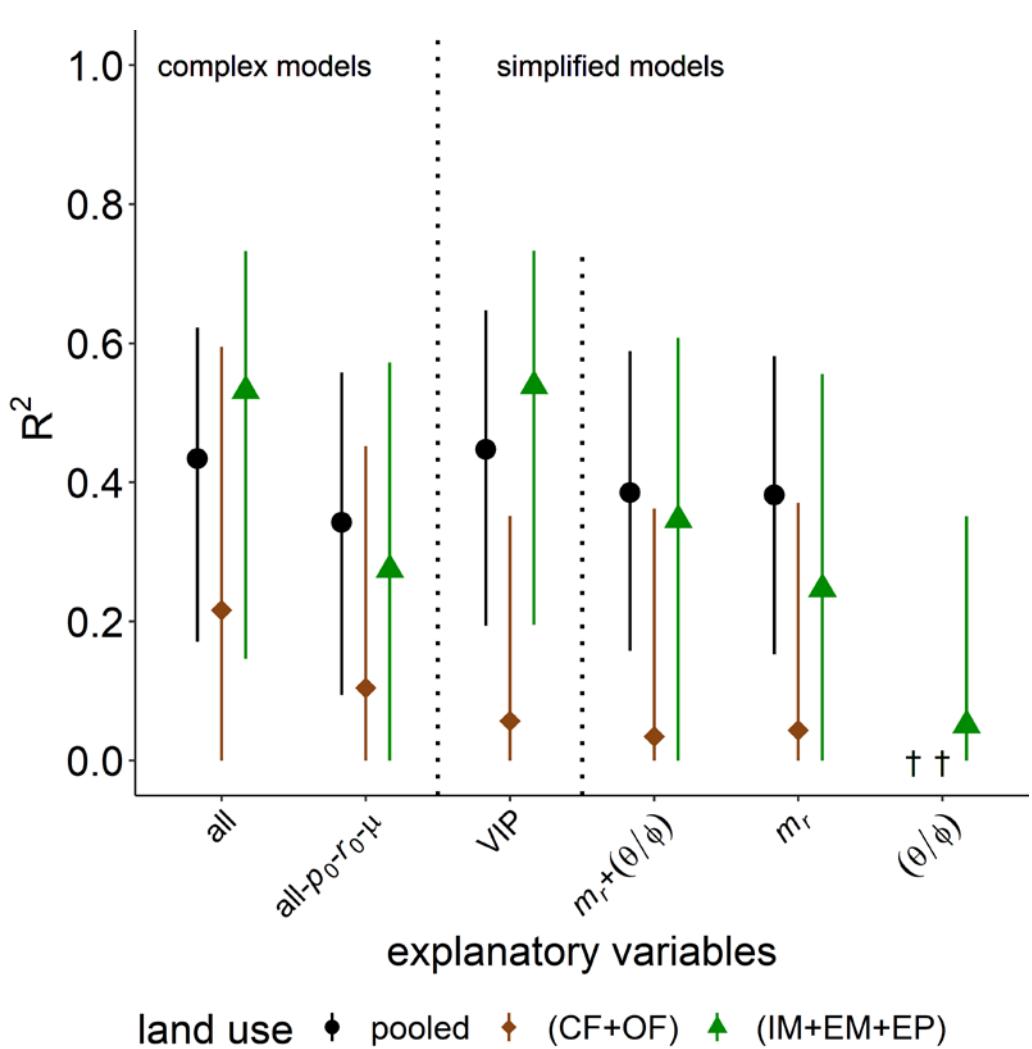

Figure 6: a) Explained variability (R^2) of basal respiration, p_b , by different combinations of explanatory variables for all land uses (pooled) or only cropland (CF+OF) and grassland (IM+EM+EP), respectively. The all- $p_{o\cdot}r_{o\cdot}\mu$ model includes all explanatory variables, except for microbial variables. The VIP model includes the variables of importance to predict p_b . (Please refer to the text for more information). † no variability explained.

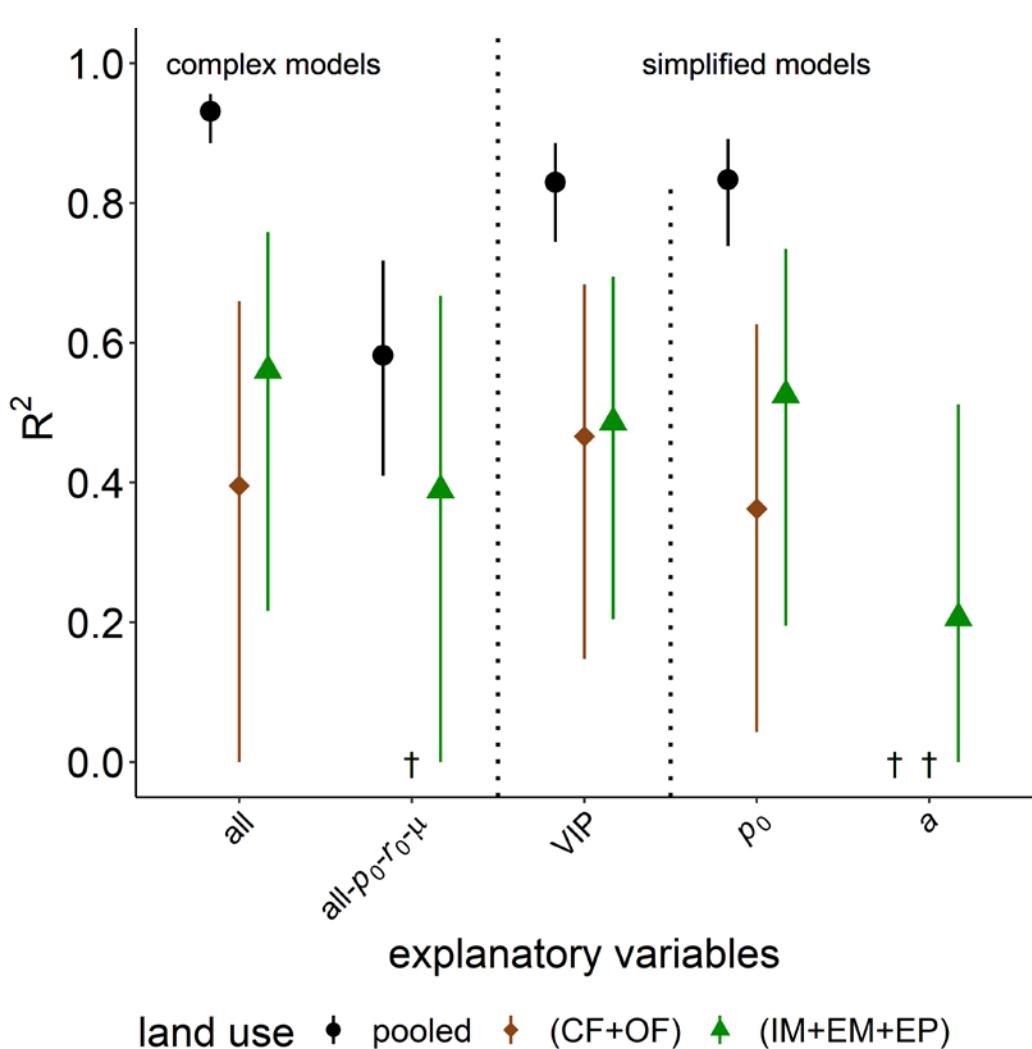

Figure 7: Explained variability (R^2) of time of capacity excess, t_{exc} , during substrate induced respiration (t_{ave}) by different combinations of explanatory variables for all land uses (pooled) or only cropland (CF+OF) and grassland (IM+EM+EP), respectively. The all- $p_o-r_o-\mu$ model includes all explanatory variables, except for microbial variables. The VIP model include the variables of importance to predict t_{exc} . (Please refer to the text for more information).[†] no variability explained.
